Chronic encephalopathies induced by mercury or lead: aspects of underlying cellular and molecular mechanisms

Lars Rönnbäck, Elisabeth Hansson

Abstract
Long term exposure to low doses of mercury or lead can induce neurasthenic symptoms with slight cognitive deficits, lability, fatigue, decreased stress tolerance, and decreased simultaneous capacity. After exposure to higher concentrations permanent neuropsychological deficits can be seen. The present paper gives a new idea of possible molecular mechanisms underlying the symptoms. Impairments of astrocyte function are probably important, especially due to their capacity to regulate the ionic and amino acid concentration in the extracellular micromilieu, brain energy metabolism, and cell volume. Recent results have shown that these functions are under monoaminergic control. Aspects of therapy are outlined.

Long term exposure to mercury may give rise to a syndrome of tremor, variable limb weakness, and ataxia due to damage of cells in the cerebellum. Also, personality changes often characterised by fatigue, stress intolerance, insomnia, irritability, and sometimes impairment of concentration capacity and of short term memory can be seen. The patients often complain of decreased simultaneous capacity and impairments in their ability to talk to several people at the same time. They also complain of increased sensitivity to sound. Similarly, exposure to low doses of lead for long periods can give rise to neurasthenic symptoms. The symptoms are important as they profoundly impair the patient’s capacity to work. The nervous system is a primary target for many toxic substances but the anatomical origins of the symptoms are at present not fully understood, although neuronal networks in large parts of the cerebral cortex are believed to be affected.

Little is known about biochemical correlates with behaviour, probably due to the prominent functional specialisation and cellular heterogeneity even in small brain regions. Neural tissue has a profound specialisation for excitability, which is the basis for brain functions. To establish and maintain this high degree of excitability it is of utmost importance that the extracellular environment is stable. This is especially important as neurones and synapses are densely packed and thus the activity of neurones could affect the activity of other neurones. It thus seems appropriate that half of the brain’s volume does not consist of excitable cells but of non-excitable glial cells. These cells have the capacity to isolate neuronal systems and to regulate the neuronal microenvironment. A large mass of evidence now exists showing that astroglia, which constitute the bulk of the glial cells in the cerebral cortex, develop abilities to regulate the extracellular environment of neurones. This ability places these cells in the adaptably important position of changing that environment and therefore modulating the excitability of many neurones simultaneously. Furthermore, these cells have a prominent capacity for oxidative metabolism and they are also considered important for the regulation of brain volume. Recent research has shown that these functions are under adrenergic control and has placed the astroglial cells, as well as neurones, in the position of possible targets for noradrenergic transmission. It was known many years ago that both mercury and lead accumulate in astrocytes and affect their function.

Astrocyte anatomy, properties, and functions
Astrocytes constitute more than half of the cell number in the cerebral cortex of higher mammals. They have long processes that surround blood vessels and synapses, form a continuous subpial and subependymal layer, surround neuronal surfaces, and form a network with other astrocytes by means of gap junctions. These gap junctions are a prominent feature of astrocytes in the brain and many lines of evidence suggest that astrocytes are electrically coupled to each other. In fact, there is evidence for a calcium channel that could regulate the permeability of gap junctions. Recently, Cornell-Bell
and coworkers\textsuperscript{20} showed that glutamate induced increases in cytoplasmic free calcium propagate as waves with the cytoplasm of individual astrocytes and between adjacent astrocytes in confluent cultures. Those propagating waves of calcium suggest that networks of astrocytes may constitute a long range signalling system within the brain. The Ca\textsuperscript{2+} waves may propagate between the cells by passage of a second messenger through the gap junctions. Potential mediators of the signalling postulated by Cornell-Bell \textit{et al.}\textsuperscript{20} include the inositol phosphates (for example IP\textsubscript{3}), some other inositol phosphate metabolites, the Ca\textsuperscript{2+} ion itself, and the flow of electric current. Furthermore, astrocytes possess voltage sensitive ion channels, such as sodium and chloride channels\textsuperscript{21} and several types of potassium channel, including one that is calcium dependent,\textsuperscript{22} and ion channels regulated by glutamate.\textsuperscript{23} Various oscillatory and non-oscillatory Ca\textsuperscript{2+} responses of astocytes to glutamate have been found.\textsuperscript{20,24} Because nerve terminals that release glutamate are close to astrocytic membranes, neuronally released glutamate may trigger Ca\textsuperscript{2+} responses in astrocytes in situ.

The cells have several important roles in the mammalian brain. For example, it is generally considered that astrocytes are involved in the maintenance of the external K\textsuperscript{+} concentration,\textsuperscript{25} guidance of migrating neurones,\textsuperscript{26} inactivation of neurotransmitters,\textsuperscript{27,28} antigen presentation to macrophages,\textsuperscript{29} and induction of the blood brain barrier.\textsuperscript{30} The astroglial cells produce and secrete trophic factors for the neurones\textsuperscript{31} and if they are severely damaged, neuronal survival might be affected. The cells are differentiated in various brain regions, and there seems to be a great heterogeneity among the astrocytes.\textsuperscript{32–36} Most of our present knowledge about properties of astroglial cells have come from studies of cell culture (fig 1).

Membrane receptors on astroglia

Astrocytes in culture possess receptors for many neurotransmitter substances. Most of those studied so far are linked to cyclic AMP or inositol phosphates as second messengers.\textsuperscript{32,37,38} Astroglial \(\beta\)-adrenoceptors are mainly of the \(\beta_1\) subtype.\textsuperscript{39} They are coupled to adenylate cyclase, which leads to increases in cyclic AMP.\textsuperscript{40–42} Astrocytes also possess \(\alpha\)-adrenoceptors that mediate an inhibition of cyclic AMP accumulation in the cells.\textsuperscript{43–45} Because \(\alpha\)-adrenoceptors inhibit the production of cyclic AMP induced by \(\beta\)-receptor stimulation, it is likely that both \(\alpha\) and \(\beta\)-adrenoceptors are expressed on the same cell\textsuperscript{45} and they probably contribute to the control of intracellular cyclic AMP concentrations.

There is strong evidence that the \(\alpha\)-receptor subtype is linked to stimulation of inositol phospholipid metabolism on astrocytes grown in primary culture.\textsuperscript{46–47} \(\alpha\)-Receptor activation thus results in mobilisation and entry of calcium and activation of protein kinase C. The work by Pearce and coworkers\textsuperscript{48} showed a stimulation of phosphoinositide hydrolysis achieved by 5-hydroxytryptamine (5HT) and we showed the presence of 5HT\textsubscript{2} receptors on astrocytes in primary culture from the cerebral cortex, striatum, hippocampus, and brain stem with a stimulation of turnover of phosphoinositides.\textsuperscript{49}

\end{figure}
cyclic AMP in the cerebral cortex. 5-hydroxytryptamine, which has no effect on the formation of cyclic AMP, potentiated the \( \beta \)-adrenergic stimulation of adenylate cyclase. The inositol monophosphate (IP1) response after simultaneous stimulation with the \( \alpha_1 \) agonist phenylephrine and 5HT was significantly larger than the sum of the individual phenylephrine and 5HT effects. Clonidine, an \( \alpha_2 \) agonist, known to lower cyclic AMP, potentiates the 5HT stimulated formation of IP1 considerably. Our observation that adrenergic and serotonergic receptors on astrocytes interact are in line with the concept of receptor receptor crosstalk as a means of processing extracellular information (fig 2).

Astrogial receptor function
Brain glycogen is stored predominantly in astrocytes. It has been shown that both noradrenergic and 5HT can evoke glycogenolysis and that noradrenergic control of glycogen metabolism is exerted through both \( \alpha \)- and \( \beta \)-receptors. Furthermore, an increased extracellular K+ concentration increased astroglial glycogenolysis. It has also been found that \( \beta \)-receptor activation stimulates glucose uptake into astroglial cells and that noradrenaline stimulates oxidative metabolism in astrocytes but not in neurones in culture. Interestingly, Magistretti and Schorderet suggested that the activation of the noradrenergic system together with VIPergic neurones causes potentiated cyclic AMP and glycogenolytic responses to produce metabolic "hot spots" in the cerebral cortex to cope with localized increases in neuronal activity.

Glutamate and \( \gamma \)-aminobutyric acid (GABA) are two of the most extensively distributed amino acid
Mercury or lead in chronic low doses: biochemical aspects of neurasthenic symptoms

The noradrenergic system is thought to play an important part in attention processes and in responses to stress. Noradrenaline is present in high concentrations in the cerebral cortex. The main source is the locus coeruleus in the brain stem (fig 4). The noradrenergic innervation of the cerebral cortex is composed of fine axons, organised predominantly in a plane parallel to the pial surface and spanning a vast expanse of the cortex.

Noradrenaline in low or moderate concentrations (fig 5A) increases astroglial GABA uptake through β-receptor activation. This leads to a decrease in extracellular GABA which, in turn, results in a decreased inhibition and the possibility of a higher level of transmission in neighbouring synapses and a higher excitation of the postsynaptic membranes. Increased extracellular K⁺, the normal result of neuronal depolarisation, triggers both pump activity and also astrocytic metabolism of glucose and glycogen. Metabolites are formed such as pyruvate and α-ketoglutarate, which are released to the neurons. Also, lactate is formed and this leads to a decrease in pH. Together with the active uptake of K⁺ and Cl⁻ by Na⁺ dependent processes, cell volume is increased. In addition, an increased glucose uptake and an increased glycogen and glucose breakdown are directly induced by β-receptor activation. It should be noted that astroglial GABA uptake is of high affinity and low velocity and therefore regulation of GABA uptake by astrocytes probably has a minor role in synaptic activity that is more modulatory in nature. β-Receptor stimulation also leads to a diminished glutamate uptake, which might allow transmitter release to generate a higher glutamate concentration at the postsynaptic site. Furthermore, a reduction of the uptake could increase the resting extracellular glutamate concentration with the result that synthetically released glutamate produces a larger postsynaptic response. Accumulated extracellular glutamate has been shown to induce gluconeogenesis with an increase in glycogen and a decrease in glucose utilisation. Although it has been shown that gluconeogenesis does not play any prominent part in the central nervous system, it might to some extent build up local energy or energy rich substances in neighbouring neuronal systems. If required, it might on the other hand, serve as a self regulating system to decrease the metabolism and thereby inhibit neuronal activity. After some period, regulatory mechanisms probably lead to an increased GABA release and, if the uptake is still high, some modulation of the synaptic activity could be expected. On the other hand, if the noradrenaline concentration is further increased, the GABA uptake through β-receptor activation (at higher concentrations) will

transmitters in the cerebral cortex. Excitatory amino acid systems using glutamate as transmitter are widely distributed in the cerebral cortex and in subcortical regions, especially in the hippocampus, frontal cortex, and in regions associated with sensory function—for example, the superior colliculus and the cochlear nucleus. Glutamate is removed from the extracellular space around synapses by an Na⁺-dependent high affinity uptake into both glia and neurones. Astroglial cells possess receptors and uptake carriers for glutamate and GABA and the uptake of glutamate by astroglia is considered to be sufficient to account for all glutamate released by neurones. It is generally thought that one role of astrocytes is to accumulate glutamate by active transport. The capacity for GABA uptake is, however, rather low. It has therefore been questioned whether this uptake has any physiological role compared with the reuptake capacity of GABAergic neurones. The glutamate and GABA carriers in astrocytes are controlled by noradrenaline (figs 2 and 3). Thus at low β-adrenergic stimulation, there is an increased GABA uptake and a decreased glutamate uptake into astrocytes whereas at higher concentrations of the β-agonist both GABA and glutamate uptakes are at the control value. At high noradrenaline concentrations, glutamate uptake is increased, mediated through activation of the α-receptors. It was also shown that the adrenoceptors regulate the intracellular enzymatic activity of glutamic oxaloacetate transaminase, glutamine synthetase, and γ-aminobutyric acid α-ketoglutarate transaminase.
concentrations and thereby increased neuronal excitability\(^7\(^3\(^4\)\); (2) a gial depolarisation with increased extracellular \(K^+\) that results in a decreased gial uptake of glutamate; and (3) an increase in volume with a decreased extracellular space and a further increase in the extracellular concentration of glutamate. Furthermore, \(\alpha_1\)-receptor stimulation has been shown to potentiate the \(\beta\)-receptor activated glycosgenolysis.\(^5\) Thus both neuronal excitability and astrogial metabolism increase, and so also does the cell volume. Hence, activation of astrogial adrenergic receptors might stimulate neurotransmission by regulation of the extracellular milieu and also the astrogial energy metabolism. The resultant decrease in pH and increase in cell volume with decreased extracellular space and increased tortuosity\(^7\) might be factors of importance in the self regulation of the stimulation.

What happens after exposure to low doses of mercury or lead? It has been shown that both mercury and lead inhibit the astrogial capacity to take up glutamate\(^7\(^5\)\(^6\)\(^6\)\(^7\) (fig 6) and even low concentrations will inhibit the activity of glutamine synthetase,\(^7\(^6\)\(^7\)\(^8\) the enzyme that converts glutamate to glutamine in astroglia.\(^4\) If there is a slowly progressing disturbance of astrogial glutamate uptake, or glutamine synthetase activity, or both, then synaptic glutamate transmission will decrease to compensate and less glutamate will probably be released. A decreased neuronal activity mostly results in an up-regulation of surface receptors\(^7\(^9\)\(^8\)\(^0\) and it might be that the glutamate receptors will become more sensitive. Under all circumstances cortical glutamate transmission probably decreases with a secondary decrease in transmission in other cortical neurotransmitter systems. As a regulatory consequence, the activity of the locus coeruleus will decrease to some extent and as far as can be expected from the role of cortical noradrenergic activity this might correspond to the symptoms that these patients report, namely, fatigue and lowered alertness.

The problems that appear if there is a prominent noradrenergic activation in this situation with a decreased astrogial uptake of extracellular glutamate can be pronounced. The glutamate concentration rises rapidly either in the whole cortex or locally. Cell volume probably increases and it seems that the biochemical changes correspond to the clinical situation of insufficiency, lability, and headache.

If on the other hand there is a less prominent noradrenergic activation then it is more probable that the glutamate transmission does not work effectively or distinctly due to delays in uptake from the synaptic space. This might lead to difficulties in activating many synapses in parallel. As cell volume probably increases somewhat the extracellular space decreases, which further augments the difficulties. These might be the biochemical correlates with the clinical situ-
system” and prevent the glutamate receptors from being down regulated too much. Furthermore, a slight β-receptor activation increases metabolism. In this context, it is interesting to take into account that stimulation of 5HT2 receptors on astroglial cells potentiate the β-receptor activated cyclic AMP. Furthermore, it was shown that 5HT2 receptor activation to some extent stimulated the α-receptor induced formation of inositol phosphate. Hypothetically, it might thus be valuable in the clinical situation to have a slight noradrenaline and a slight 5HT activation even though more specific receptor stimulation is required.

Exposure to even higher mercury or lead concentrations might severely affect astroglial uptake and give rise to a prominent increase in extracellular glutamate concentration. As high extracellular glutamate is cytotoxic sensitive neurones might be damaged, especially neurones in the CA1 region in the hippocampus, resulting in memory disturbances and other permanent cognitive deficits.

Conclusions
Recent research on astroglia characteristics carried out mostly on cell culture models has shown that these cells, intimately associated and intermingled with other neuroglia and with neurones, serve important functions in regulating the extracellular microenvironment, including neuronal excitability and metabolism. The cells serve supportive and protective functions towards the neurones and they have a great capacity for regulation of volume. From this view, a behavioural model is presented that enlightens cellular and molecular mechanisms hypothetically underlying symptoms of non-focal encephalopathy such as increased fatigue, stress intolerance, and a slightly decreased cognitive capacity. The hypothesis presented is based on many lines of evidence suggesting that astroglia are targets for noradrenergic and serotoninergic activation and thereby regulate the neuronal extracellular milieu including amino acids—for example, glutamate—and ions—for example, Ca²⁺, K⁺, and Cl⁻, and Na⁺. Impairment of these astroglial functions, especially the high affinity glutamate uptake, by mercury or lead might lead to a less distinct glutamate transmission and a glutamate “overflow” that could result in the clinical symptoms. At higher metal concentrations the astroglial glutamate uptake is impaired even more and the extracellular glutamate might reach concentrations that are cytotoxic to neurones. Some brain regions, especially the CA1 pyramidal cells in the hippocampus are especially vulnerable, probably due to their high density of N-methyl-D-aspartate receptors. Slight noradrenaline and 5HT activation may help the clinical situation.
