Guberan, E. and Fernandez, J. (1974). *British Journal of Industrial Medicine*, 31, 159-167. **Control of industrial exposure to tetrachloroethylene by measuring alveolar concentrations: theoretical approach using a mathematical model.** The uptake, distribution, and elimination of tetrachloroethylene were studied using a mathematical model, and predicted alveolar concentrations were compared with experimental data. Because of its high fat solubility the solvent accumulated in adipose tissue with a predicted biological half-life of 71.5 hours. The relation between the alveolar concentrations and the level or duration of exposure was discussed. The alveolar concentrations of tetrachloroethylene during and after similar exposure were predicted in subjects who differed in age, body weight, height, and body fat content, both at rest and during physical effort. Predictions were made of the alveolar concentrations following exposures to steady and variable concentrations in ambient air, and following exposures of several weeks of the type occurring in industry. It was concluded that measurement of the postexposure alveolar concentrations could be used to estimate the mean exposure to tetrachloroethylene in most industrial situations.

As a result of previous studies of several industrial solvents (Riley, Fassett, and Sutton, 1966; Stewart, Baretta, Dodd and Torkelson, 1970; Stewart, Dodd, Gay, and Erley, 1970; Reinhardt, McLaughlin, Maxfield, Mullin, and Smith, 1971; Azar, Reinhardt, Maxfield, Smith, and Mullin, 1972; Di Vincenzo, Yanno, and Astill, 1972; Hunter and Blair, 1972; Sherwood, 1972) and our study of tetrachloroethylene (Fernandez and Guberan, 1974), the question arose as to whether alveolar air measurements could be used to control industrial exposure.

In this paper a mathematical model has been developed to predict uptake and distribution of tetrachloroethylene in the body and its elimination in the alveolar air. Various situations likely to arise in industry have been simulated.

Methods

Physiological parameters

In order to be able to compare measured and predicted results, the mean values of our 25 experimental subjects (Fernandez and Guberan, 1974) for age, body weight, and height were taken as the values of a standard man (Table 1). His cardiac output, blood volume, respiratory frequency, and functional residual capacity were calculated from the tables in the literature (Brandfonbrener, Landowne, and Shock, 1955; Sjöstrand, 1962; Cotes, 1965), and the ventilation-perfusion ratio was assumed to be 1.

Tissue groups

Body tissues were grouped according to Eger (1963a) into four compartments—the vessel-rich group (VRG) (corresponding to brain, heart, hepatoportal system,

kidneys, and endocrine glands), the muscle group (MG) (muscle and skin), the fat group (FG) (adipose tissue and yellow marrow), and the vessel-poor group (VPG) composed of the connective tissue (bone, cartilage, ligaments, etc.), and also the lung tissue, with a volume of 0.5 litre. The volume and perfusion of each tissue group are given in Table 2.

Partition coefficients

The blood-gas partition coefficient of tetrachloroethylene is about 9 (Morgan, Black, and Belcher, 1970). Its oil-blood coefficient is unknown but probably close to that of trichloroethylene, which is 107 (oil-gas coefficient 960 (Mapleson, 1963)) and average blood-gas coefficient about 9 (Morgan *et al.*, 1970; Mapleson, 1963). We have no data on the other tissue-blood partition coefficients and it was assumed that they approach those given by Eger (1963a) for the highly fat soluble halothane which are respectively 2.5, 3.5, and 1.0 for the VRG, the MG, and the VPG.

Quantitative analysis

The above data were used in the mathematical model the equations of which are given in the Appendix. A program to solve this system of equations was written in Fortran IV. Biotransformation of tetrachloroethylene is only of the order of 2% (Daniel, 1963; Ogata, Takatsuka, and Tomokuni, 1971) and was therefore neglected.

Results and discussion

Uptake and elimination by the tissue groups

As can be seen in Fig. 1, predicted uptake of tetrachloroethylene by the tissue groups is related to their perfusion rate (Table 2). In the VRG (75% of the cardiac output) peak uptake rate occurs in the first minutes and uptake falls to a negligible level after about 60 minutes. This corresponds to the time necessary to saturate this group of tissues (when the partial pressure or tension in the tissues equilibrates with that in the arterial blood, as shown in Fig. 2). For the less perfused MG and VPG, peak uptake rate is reached after about 30 minutes, and equilibrium between tissue and arterial tensions does not occur within 8 hours. In the fatty tissue, because of its high tissue-blood partition coefficient, the increase of uptake rate is slower and the level of tension much lower than in other tissues.

During elimination an inverse scheme occurs with a rapid depletion of the VRG, a slower one for the MG and the VPG, and a very slow release of solvent

FIG. 1. Predicted uptake rate of tetrachloroethylene by the tissue groups and the whole body during 8 hours' exposure to 100 ppm.

TABLE 2
VOLUME, PERFUSION, AND PARTITION COEFFICIENT OF THE FOUR TISSUE GROUPS

	Tissue group

Tissue-blood partition coefficient	2.50	3.50	107.00	1.00

¹Eger (1963a)

from the FG, starting only 8 hours after the end of exposure.

From the whole body uptake rate curve of Fig. 1 the retention ν time can be calculated since the weight of tetrachloroethylene inspired per minute is 4.1 mg. Initial retention is high (91%) and decreases to 36% at the end of the 8 hours. During the whole period the retention is 48%.

Alveolar partial pressure curve

During exposure, the alveolar tension curve of tetrachloroethylene has three distinct phases—a rapid initial rise (first 20 minutes), an inflection (20–60 minutes), and a progressively slow rise towards the constant tension in ambient air (Fig. 2). Similar phases are observed for any inert gas inspired at a constant tension, differences in the duration of the phases being related to the blood and tissue solubility peculiar to each gas (Kety, 1951).

FIG. 2. Predicted partial pressure of tetrachloroethylene in alveolar air, mixed venous blood, and tissue groups during and after 8 hours of steady exposure.

Partial pressures in alveoli, blood, and tissues (P) is expressed as a fraction of the constant partial pressure in ambient air during exposure (P_{insp}).

These phases are related to the exchanges of the solvent occurring simultaneously in the body (a) between ambient air and alveolar gas, (b) between alveolar gas and pulmonary blood, and (c) between peripheral blood and tissue groups. The first phase corresponds to a high uptake rate for exchanges (a), (b), and (c), the respective tension gradients being high. As the VRG becomes saturated, venous tension rises rapidly with a corresponding decrease of alveolar-venous tension gradient and a rapid rise of alveolar tension. The inflection of the curve

(second phase) corresponds to the final phase of the VRG saturation. During the third phase the progressively low increase of alveolar tension is related to the lower respective tension gradients and therefore the lower uptake rates for exchanges (a), (b), and (c).

During elimination the same three phases occur with the fall of alveolar tension and would give the mirror image of the alveolar curve during uptake if complete saturation had occurred.

Biological half-life

The actual distribution of the solvent to the tissue groups during and after 8 hours of exposure to 100 ppm is shown in Figure 3. At the end of exposure half of the solvent taken up by the body has been distributed to the fatty tissue, due to its high tissue-blood partition coefficient and despite its still low tissue tension. The respective distribution of the solvent to the other tissue groups is related to their volume and partition coefficient and therefore is higher for the MG than for the VRG and the VPG. After exposure, the depletion of these three groups of tissues is almost complete after about 20 hours and the ensuing elimination in alveolar air is related to the slow release of solvent from adipose tissue. Beyond about 20 hours of elimination the rate of discharge of the tetrachloroethylene from the adipose tissue and therefore from the whole body is an exponential function of time, predicted biological half-life being 71.5 hours.

FIG. 3. Predicted distribution of tetrachloroethylene to the tissue groups during and after 8 hours' exposure to 100 ppm.

Level and duration of exposure

Alveolar concentration (as well as partial pressure) ν time is proportional to the level of exposure since, according to Kety (1951), the shape of the curve

of alveolar saturation and desaturation of an inert gas is independent of the constant inspired concentration.

This law no longer applies to higher inspired concentrations than those usually met in industry, as shown by Eger (1963b) for anaesthetic gases. As we have seen, alveolar concentration is not proportional to the duration of exposure since its rise is much more rapid during the first phase of uptake. This is of practical importance since, in industrial hygiene control, level and duration of exposure have apparently the same 'weight.' In fact, the total quantity of tetrachloroethylene taken up by a continuous monitoring instrument will be the same for exposures of 8 hours to 50 ppm or of 4 hours to 100 ppm. But this does not correspond to the same quantity of solvent penetrating the body as 3 hours 15 minutes are sufficient to reach half of the whole body uptake during 8 hours (Fig. 3). In addition, if the tetrachloroethylene concentration in the brain and other organs such as liver and heart (the VRG) is responsible for the symptoms of poisoning, it should be noted that the concentration in the VRG after 34 minutes of exposure is already half that reached in 8 hours (Fig. 2).

Comparison with experimental data

The accuracy of the many mathematical models used to predict uptake and distribution of various anaesthetics has been recently discussed by Cowles,

FIG. 4. Alveolar concentrations of tetrachloroethylene after 8 hours of steady exposure. Comparison of the computed curve of a standard man and the experimental data of four subjects.

Alveolar concentrations (C_{Alv}) are expressed as a fraction of the constant concentration in ambient air during exposure (C_{Insp}).

FIG. 5. Alveolar concentrations of tetrachloroethylene after 2 hours of steady exposure. Comparison of the computed curve of a standard man and the experimental data (Fernandez and Gubaran, 1974) of six subjects.

Borgstedt, and Gillies (1972). In our model, we had to assume that the tissue-blood partition coefficient for adipose tissue was the same as that for trichloroethylene. For the other tissue groups we chose the most probable partition coefficient. Our results (Figs 4 and 5) show that the computed curves described hereafter are of the same order of magnitude as the real ones.

Repeated exposure

In industry, exposure often occurs Monday to Friday, 4 hours in the morning (8 to 12 am) and 4 hours in the afternoon (1 to 5 pm). Due to the incomplete elimination of the solvent from fatty tissue during the night (other tissues being almost depleted during this period) the alveolar concentration curve shows a slight daily increase during the week (Fig. 6).

When such exposure is repeated during several weeks, the uptake by fatty tissue during the working hours of the week will equal the elimination during the nights and the weekend from the fourth week on. Then, the Monday to Friday 8 am partial pressure in fatty tissue will vary from 15% to 23% of the constant partial pressure in ambient air, and the partial pressure in alveolar air from 5% to 8% (Fig. 7). This is the case for all of the following weeks of the year (Table 3). For an industrial exposure to a constant concentration of 100 ppm the range of predicted concentrations is 96 mg to 168 mg of tetrachloroethylene per litre of fatty tissue from Monday morning to Friday evening, from the fourth week on.

During a three-week holiday the fatty tissue and therefore the whole body depletion will be almost complete since the biological half-life of tetrachloroethylene is about three days for this tissue.

FIG. 6. Predicted alveolar concentrations of tetrachloroethylene for an 'industrial' exposure of one week. Exposure time 8-12 am and 1-5 pm, Monday to Friday.

FIG. 7. Predicted partial pressures of tetrachloroethylene at 8 am in fatty tissue and alveolar air for an 'industrial' exposure of four weeks. Exposure time 8-12 am and 1-5 pm, Monday to Friday.

Differences in body weight, height, and age

Computed curves of alveolar concentration for subjects of different age, body weight, and height, and with similar exposure, are shown in Figure 8. Other physiological parameters were calculated as for our standard man. Alveolar concentrations are slightly affected by the differences in body weight and height, as can be expected, since not only

ventilation but other parameters such as cardiac output, volume of tissue groups, and blood volume are also different. The decrease of cardiac output (Brandfonbrener *et al.*, 1955) and ventilation with age lowers alveolar concentrations to a slightly greater extent. Nevertheless, even the addition of both factors has a negligible influence on the post-exposure alveolar curve of the solvent.

Physical effort

The effect of doubling the ventilation in the same subject during a physical effort is shown in Figure 9. For the 14 litres/min of alveolar ventilation, the cardiac output was assumed to be 11 litres/min (Asmussen, 1965) and the frequency of respiration 18/min (Cotes, 1965). If the higher ventilation continues during the postexposure period the higher uptake is compensated by a faster elimination and both postexposure curves differ slightly.

Obesity

If our standard man was obese so that he had a double volume of fatty tissue (29 litres), his body weight would be about 85 kg. The physiological

TABLE 3

PREDICTED POSTEXPOSURE ALVEOLAR CONCENTRATIONS OF TETRACHLOROETHYLENE AS A FRACTION OF THE CONSTANT CONCENTRATION IN AMBIENT AIR (C_{Alv}/C_{Insp}) FOR DIFFERENT DAYS OF THE WEEK (Exposure time 8-12 am and 1-5 pm, Monday to Friday; values apply to the fourth and the following weeks of exposure.)

Day of the week	Postexposure time				
	0 min 5 pm	30 min 5.30 pm	1 hr 6 pm	2 hr 7 pm	15 hr 8 am next day
Monday	0.60	0.32	0.28	0.23	0.06
Wednesday	0.62	0.34	0.30	0.24	0.08
Friday	0.63	0.35	0.31	0.25	0.08

FIG. 8. Predicted alveolar concentrations of tetrachloroethylene for four subjects of different age, body weight, and height.

parameters were calculated for that body weight in the same manner as before. Since more blood would be drained to the fatty tissue, the percentage of the cardiac output to tissues was estimated to be 71.1%, 17.2%, 10.3%, and 1.4% for the VRG, MG, FG, and VPG respectively. As expected, obesity will lower the alveolar concentrations during uptake but slow down the elimination. Nevertheless, as shown in Fig. 10, differences of alveolar concentration during elimination between normal and obese subjects are relatively small.

Variation of inspired concentration

Figure 11 shows computed curves of alveolar concentration for an exposure which alternates hourly between 50 ppm and 150 ppm, or between 150 ppm and 50 ppm during 8 hours, and that for a steady exposure to 100 ppm for the same period. Mean exposure being the same, the hourly variations have little influence on the postexposure curve. However, this result does not apply to conditions where the concentrations fluctuate too much during exposure. In that case, the postexposure alveolar concentrations might be more influenced by the concentration in ambient air during the last period of exposure than by the mean exposure.

Alveolar concentrations (C_{Alv}) are expressed as a fraction of the mean concentration in ambient air during exposure (C_{Insp}). — 8 hr to 100 ppm; — — — alternatively 1 hr to 50 ppm, 1 hr to 150 ppm; — · — · — alternatively 1 hr to 150 ppm, 1 hr to 50 ppm.

Comment

Our results show that interindividual differences in age, body weight, height, body fat content, and physical effort, as well as moderate fluctuations around the mean concentration of tetrachloroethylene in ambient air, have an almost negligible influence on the predicted postexposure alveolar curve of this solvent. This curve shows a slight daily increase during the week following industrial exposures for 8 hours daily, Monday to Friday. In view of these findings the measurement of post-exposure alveolar concentrations can be used to give a reliable estimate of the mean exposure, as shown in Figure 12. We believe that such a method could be widely applied in controlling exposure to tetrachloroethylene and to other inert vapours and gases in industry, provided the concentrations in ambient air do not vary too much during exposure.

Use of graph (Fig. 12): First measure the actual alveolar concentration of tetrachloroethylene, determine the duration of exposure and the time of measurement from the beginning of the postexposure period. Then start with exposure duration on the horizontal axis. Follow a vertical line to the postexposure time curve and from this point, along a horizontal line, find on the left the ratio C_{Alv}/C_{Insp} . This is the ratio of the actual alveolar concentration to the mean concentration of tetrachloroethylene in the ambient air to which the subject was exposed.

FIG. 12. Predicted postexposure alveolar concentrations of tetrachloroethylene at various times, against duration of exposure. Alveolar concentrations (C_{Alv}) are expressed as a fraction of the mean concentration in ambient air during exposure (C_{Insp}). See paragraph above.

APPENDIX

Mathematical model

During each respiratory cycle (the duration of which is dt) exchange of solvent occurs until the state of equilibrium is reached:

I between compartment 1 = alveolar gas, and compartment 2 = pulmonary blood + lung tissue
 II between compartment 1' = peripheral blood, and compartment 2' = body tissues (divided in four tissue groups).

According to Henry's law, equilibrium I depends on the blood-gas partition coefficient 1 of the solvent, and equilibrium II on the tissue-blood partition coefficient (for each tissue group).

This exchange can be summarized by the following equations:

$$C_1 V_1 + C_2 V_2 = w_{1_0} + w_{2_0}$$

$$w_1 = C_1 V_1$$

$$w_2 = \lambda C_1 V_2 = C_2 V_2$$

where V_1 and V_2 are the volumes of the compartments, w_{1_0} and w_{2_0} are the quantities of solvent in the compartments before equilibration, C_1 and C_2 are the final concentrations, w_1 and w_2 the final quantities of solvent in the compartments after equilibration, and λ is the partition coefficient.

(1) The lung tissue-gas partition coefficient is assumed to be the same as the blood-gas partition coefficient (Eger, 1963a).

For equilibrium I:

V_1 = effective tidal volume (V_A) (tidal volume minus dead space) + pre-inspiratory gas volume (V_p) (corresponding to the functional residual capacity)

w_{1_0} = weight of solvent in V_A inspired at the beginning of dt (= $V_A \cdot C'_{\text{Insp}}$ (2)) + weight of solvent remaining in V_p at the end of the preceding respiratory cycle

C_1 (3) and w_1 = concentration and weight of solvent in V_1 after equilibration

V_2 = volume of capillary blood exposed to alveolar air during dt (Q_c) + volume of lung tissue

- w_{2_0} = weight of solvent in a volume Q_c of the mixed venous blood returning to the lungs (w_v) at the end of the preceding 'circulatory cycle' (4) + weight of solvent remaining in the lung tissue at the end of the preceding respiratory cycle
- C_2 = concentration of solvent in pulmonary blood and lung tissue after equilibration
- w_2 = weight of solvent in pulmonary blood (w_c) + that in lung tissue, after equilibration
- λ = blood-gas partition coefficient.

(2) The concentration of solvent (C_{Insp}) in the ambient air of the exposure chamber (18°C, relative humidity 50%, pressure 720 mmHg) was corrected to that (C'_{Insp}) in the air penetrating the lungs (37°C, saturated with water vapour) according to the relation:

$$C'_{\text{Insp}} = \frac{720 - 47}{720 - 8} \cdot \frac{273 + 18}{273 + 37} C_{\text{Insp}} = 0.89 C_{\text{Insp}}.$$

(3) Corresponding to C_{Alv} in the figures.

(4) See below.

For equilibrium II (for each tissue group):

- V_1 = volume of blood perfusing the tissue group during dt (which is a fraction of Q_c given by the % of cardiac output perfusing the tissue group, see Table 2).
- w_{1_0} = weight of solvent in V_1 before equilibration (which is a fraction of w_c calculated as above)
- V_2 = volume of the tissue group
- w_{2_0} = weight of solvent in V_2 at the end of the preceding respiratory cycle
- C_1, C_2 , and w_1, w_2 = respective concentrations and weights of solvent in V_1 and V_2 after equilibration
- λ = tissue group-blood partition coefficient.

In this model ventilation is treated as a cyclic process, a volume $Q_c (= Q/f)$ of blood being exposed to alveolar air during each respiratory cycle. If Q is the blood volume and Q_{c1} the blood passing through the lungs during the first respiratory cycle, the time between two passages of Q_{c1} (or the duration of a 'circulatory cycle') corresponds to $Q/Q_c (= n)$ respiratory cycles. The computer program equilibrates Q_{c1} (arterial) with tissue groups immediately after the former has left the lungs (Q_{c1} is divided into four fractions in proportion to the per cent of cardiac output to each tissue group). Then the four fractions of Q_{c1} (venous) are combined when leaving the tissues and queued for n respiratory cycles before the next equilibration with the lungs. Therefore the sum of w_1 of the four tissue groups will give the value of w_v , n respiratory cycles later. The same is done for $Q_{c2}, Q_{c3}, \dots, Q_{cn}$ corresponding to the blood passing through the lungs during the second, third, ... n^{th} respiratory cycle. At the $n^{\text{th}} + 1$ respiratory cycle, with the beginning of the second 'circulatory cycle', the second equilibrium of Q_{c1} with alveolar gas occurs.

The assumptions on which such a mathematical model is based have been discussed by several authors (Eger, 1963a; Mapleson, 1963; Kety, 1951; Cowles *et al.*, 1972). The main assumptions are: (a) there is no limitation of diffusion between alveolar gas and pulmonary blood or between peripheral blood and tissue groups, and equilibrium is reached almost instantaneously; (b) alveolar ventilation, rates of blood flow, and other physiological or physical parameters are constant unless stated otherwise; (c) concentration within each compartment, particularly within each tissue group, is uniform; (d) there is no diffusion of solvent between tissue groups; (e) there are neither unventilated alveoli nor arteriovenous shunts; (f) the respiratory quotient is 1.
