Occupational exposure of midwives to nitrous oxide on delivery suites

K A Henderson, I P Matthews, A Adisesh, A D Hutchings

Aims: To compare environmental and biological monitoring of midwives for nitrous oxide in a delivery suite environment.
Methods: Environmental samples were taken over a period of four hours using passive diffusion tubes. Urine measurements were taken at the start of the shift and after four hours.
Results: Environmental levels exceeded the legal occupational exposure standards for nitrous oxide (100 ppm over an 8 hour time weighted average) in 35 of 46 midwife shifts monitored. There was a high correlation between personal environmental concentrations and biological uptake of nitrous oxide for those midwives with no body burden of nitrous oxide at the start of a shift, but not for others.
Conclusions: Greater engineering control measures are needed to reduce daily exposure to midwives below the occupational exposure standard. Further investigation of the toxicokinetics of nitrous oxide is needed.

Nitrous oxide is used as an analgesic during labour. A number of epidemiological studies have linked occupational exposure to nitrous oxide with spontaneous abortions, congenital abnormality, and reduced rates of fertility, including reported effects in midwives. The evidence is equivocal due to problems associated with verification of exposure and validation of reproductive events. Nevertheless this evidence, as well as the known effects of nitrous oxide on folate synthesis, has influenced the setting of occupational exposure standards (OES).

In the UK the (OES) set for nitrous oxide is 100 ppm over an eight hour time weighted average (TWA). There are also requirements to have 5–6 air changes per hour within delivery rooms to control levels of waste anaesthetic gas. High levels of nitrous oxide have been reported in delivery rooms, and a previous survey of levels of nitrous oxide in healthcare facilities had identified midwifery suites as being a particular problem. This made use of direct reading instrumentation, and so was expensive in manpower resource; it was therefore decided to investigate the potential usefulness and acceptability of passive environmental sampling to measure exposures in midwifery.

In order to deliver samples to the laboratory on the day of sampling, the sampling period was chosen to be four hours (that is, half a shift) rather than eight hours. Therefore each midwife wore a passive sampling tube for the first four hours of their shift, which was placed on the lapel within the breathing zone. The steel tube was packed with molecular sieve 5A supplied by Markes International, with a diffusive cap on the top. Urine samples were collected at the start of the shift to obtain a baseline measurement; at the end of the four hour monitoring period each midwife provided a second sample. Midwives completed a simple questionnaire, which asked for information on smoking, and alcohol consumption in the past 24 hours, and what medication, if any that the midwife was taking. The questionnaire also asked which delivery rooms the midwife had attended during the monitoring, how many births were involved, and whether nitrous oxide was used. Where nitrous oxide had been used, the midwife was asked to estimate the length of time of use and how long they had been present in the room during use.

At the end of the monitoring period the passive sampling tube was sealed and sent for analysis by thermal desorption and gas chromatography. Environmental sampling tubes were thermally desorbed at 165°C in forward flush direction for three minutes with a flow rate of 30 ml/min helium using a Perkin-Elmer ATD-400. Analysis was performed using a Perkin-Elmer Autosystem XL gas chromatograph. A 60 m × 0.32 mm Gas Pro column was used with inlet pressure of 22 psi helium. The oven programme was: 10 minutes isothermal at 150°C, 250°C for 2 minutes post-run; nitrous oxide elutes at 7.2 minutes. Detection was by electron capture at 340°C. For calibration, a static 2% gas mixture in air was prepared by syringe addition of 20 ml nitrous oxide to an IL calibrated glass flask. Clean molecular sieve 5A tubes were fitted to a spare ¼ inch GC port and purged with helium. Aliquots of 0.01–10 ml of the diluted nitrous oxide mixture were injected into the calibration tubes.

METHODS
In hospital 1, 15 midwife shifts were monitored, two of which were the same individual. In hospital 2, 35 midwife shifts were monitored; 20 individuals were monitored on one occasion only, four individuals were monitored on two occasions, one on three occasions, and one on four occasions.

Abbreviations: TWA, time weighted average; OES, occupational exposure standard
Urine was collected in a sample bottle with a screw cap. Sterile receptacles were provided for convenience of urine collection, with subsequent decanting into the sample bottle. Once the sample had been collected, it was taken to the laboratory, where it was either analysed straight away or put into the freezer. Where samples were taken from the afternoon shift, the second samples were put into a freezer for storage overnight. Determination of nitrous oxide concentration in urine was by headspace analysis and gas chromatography, and followed the procedure published by Sonander and colleagues. A 10 ml urine sample was taken from the sample bottle directly into a 20 ml gas tight vial equipped with a silicone septum. The gas tight vial was incubated in a water bath at 37°C for 20 minutes, and then a 50 µl sample of the headspace gas above the urine was taken using a gas tight syringe and injected directly into the gas chromatograph. All such gas chromatograph injections were performed in triplicate. The gas chromatograph was a Hewlett Packard 5890, Series 2, fitted with Electron Capture Detection. An HP Plot Q, 30 m × 0.53 mm ID column was used; the carrier gas was 5% methane in argon with molecular sieve and oxygen trap. Conditions were: column flow rate 6 ml/min, split vent 30 ml/min, septum purge 3 ml/min, auxiliary gas 50 ml/min, anode purge 3 ml/min, oven temperature 30°C, injector temperature 80°C, and detector temperature 250°C. The retention time for nitrous oxide was 3.8 minutes. External calibration was performed by injecting 50 µl nitrous oxide calibration gas (24 ppm in air) supplied by Alltech. The reproducibility associated with sampling and analysis was determined by taking three samples from a number of individuals on several occasions for each type of sampling.

Ventilation checks were carried out in each of the delivery rooms in both the hospitals monitored, by monitoring the decay of a marker gas using an infrared spectrophotometer. Data were analysed using the Statistical Package for Social Sciences (SPSS), version 10.

RESULTS

In the sample of 46 midwives over the four hour measurement period, five midwives had TWA exposures in excess of 10 times the OEL, five in excess of 5 times the OEL, 13 in excess of 2 times the OEL, and of the 46 midwives, only 13 had TWA exposures below the OEL. The interindividual environmental concentrations were in the range 2.4–1300 ppm, with a mean level of 313 ppm and standard deviation of 358. The coefficient of variation of measurement of repeated samples from an individual was 3–4.8% over the concentration range 10–150 ppm. For urine sampling the coefficient of variation was 6.7%.

In only three midwives was there no nitrous oxide present in the urine after a four hour period. Twenty two midwives had non-zero values of nitrous oxide in their baseline urine samples (that is, immediately before starting their shift); 12 of these had concentrations of nitrous oxide in excess of 27 µg/l, which is the biological exposure limit in Italy. In five of these, four from hospital 1 and one from hospital 2, the baseline urine concentrations were higher than those found in the second sample after four hours occupational exposure. We were not able to identify any significant differences between the working environment or work practices between the two hospitals, which could explain why a greater number of midwives in hospital 1 came into this category. The non-zero baseline urinary concentrations were in the range 3–174 µg/l, with a mean concentration of 44 µg/l and standard deviation of 51 µg/l.

The unexpected observation of non-zero values of nitrous oxide in the baseline urine values of approximately half of the midwives sampled, and of high values for 12 of these raises questions concerning the value of a routine occupational monitoring programme for urinary measurement of nitrous oxide. It also complicates interpretation of the interrelationships between final urinary concentration and personal environmental concentration.

To explore occupational exposure in the total sample, for each individual the baseline value of urinary concentration was subtracted from the final value of urinary concentration. This will skew the data in a manner dependent on the kinetics of tissue clearance of nitrous oxide present in their urine at the start of a shift; a further complication was that for five midwives the baseline urine concentrations were higher than the final concentrations.

Figure 1 presents environmental levels and urinary levels of nitrous oxide for 46 midwives. The relation is described by the regression equation:

\[ \text{Urinary concentration} = 0.275 \times \text{environmental concentration} \]

The urinary concentrations in the second urine samples were in the range 0–1102 µg/l (mean 114 µg/l, standard deviation 191 µg/l). Twenty eight midwives had urinary concentrations in excess of 27 µg/l in their second sample.

The ventilation checks carried out showed that in hospital 1, eight of nine, and in hospital 2, six of 11 did not meet the requirements of 5–6 air changes per hour. Neither delivery suite had working access to scavenging systems for nitrous oxide.
prevalence of UTI in women; furthermore, not all UTI is
in our sample of midwives is much higher than the
oxide. However, the prevalence of high levels of nitrous
nitrite during urinary tract infections (UTI) can produce nitrous
negative bacilli which may be present in the urinary tract
likelihood of nitrous oxide in baseline urine is perhaps that tissue
clearance occurs over much longer time periods than has
previously been thought. Thus the 22 non-zero baseline
values may relate to previous but recent occupational
exposure. The 24 zero baseline values would then relate to
women who have not been as recently occupationally
exposed, and there may be an unrecognised accumulating
effect of exposure.

The presence of nitrous oxide in baseline urine complicates
an evaluation of the relations between environmental
exposure and uptake as measured by urinary concentrations.
In order to explore this, the group of 24 midwives with no
nitrous oxide in their baseline have been analysed separately,
as well as examining the group as a whole.

For the 24 midwives there was a high correlation between
personal environmental exposure and urinary concentra-
tions. This shows that a TWA personal environmental sample
is a good measure of integrated biological uptake for women
with no nitrous oxide in their urine at baseline.

The occupational exposure limits in the UK relate to
environmental levels, but ideally these should relate to the
measure that actually reflects uptake—that is, urinary
concentration. These data show that there is a need to
explore the kinetics of nitrous oxide absorption over the sort
of time scales of relevance in occupational health practice.
This will require tracking a number of individuals over a
period of days, spanning both occupational exposure days
and non-occupational exposure days. Urine could be sampled
periodically, and the role of accumulated uptake and
washout explored on the basis of shift pattern and exposure.

CONCLUSION
Monitoring for nitrous oxide exposure by personal environ-
mental sampling using passive diffusion tubes, or by
collection of urine samples, was found to be acceptable to
midwives and was convenient. The use of analytical gas
chromatography for determination of nitrous oxide in urine
samples and environmental samples is accurate and suffi-
cient for this purpose. The reproducibility of each type of
sampling was also satisfactory. Our data show that midwives
are routinely exposed to levels of nitrous oxide in excess of
the occupational exposure limit (OEL). Environmental
control measures and/or changes in work practices will be
necessary to reduce the high environmental levels observed;
environmental monitoring may be undertaken to check the
efficacy of such measures in reducing environmental levels.

There is a high correlation between environmental
exposure measurements and measures of biological uptake
(that is, urinary concentrations) for midwives with no
nitrous oxide in their urine at the commencement of their
shift. However, we observed approximately half of the
midwives studied to have significant levels of nitrous oxide
in their urine at baseline. Thus it would appear that nitrous
oxide is not cleared from the body as quickly as previously
thought. Consequently, depending on exposure patterns and
shift patterns, an individual may accumulate body burden of
nitrous oxide. This may occur for an individual, even if
environmental measurement falls below the OEL. We suggest
that urine samples pre- and post-shift will allow a reliable
estimate of nitrous oxide exposure for persons who have
none detectable in the pre-shift sample. In the case of nitrous

Out of the 46 midwife shifts monitored, on six occasions
the midwife attended two delivery rooms, and therefore
correlation between exposure and the ventilation of the
delivery rooms was not possible. For the remaining 40
midwife shifts monitored, the midwife remained in one
delivery room for the duration of the monitoring period. In
hospital 1, the midwife only attended one delivery room on
11 monitoring occasions. All the rooms monitored had
ventilation rates below those recommended. In hospital 2,
the midwife only attended one delivery room on 29
monitoring occasions. Of the delivery rooms monitored, four
had ventilation rates below those recommended.

DISCUSSION
Nitrous oxide is considered to be of low solubility in blood or
in other biological tissues. During absence overnight from the
work environment, occupational dose should be completely
cleared out of the body storage reservoirs.

We found that approximately half of our samples of 46
midwives had non-zero baseline values of nitrous oxide in
urine, of which 12 had very high levels.

The kinetics of absorption of nitrous oxide and then tissue
clearance are not known quantitatively. It is known that
nitrous oxide is eliminated in the kidney by a diffusion
process determined by the equilibration of partial pressures
in urine and plasma. As a result, the concentration of nitrous
oxide in urine is independent from urine output, and urine
leaving the kidneys equilibrates with gas in arterial blood
with the bladder serving as a collecting and mixing vessel.
Thus urinary concentration can be considered as an
integrator over time, which indicates uptake over the
duration of exposure.

Pre-shift urine samples were collected as soon as the
midwife appeared on the delivery suite. Since urinary
concentration is an integrator over time, any brief adventi-
tious exposure of a midwife to nitrous oxide between entry to
the hospital and reporting to the delivery suite is highly
unlikely to have altered the concentration in the urine in the
bladder.

It has been suggested in the literature that certain Gram
negative bacilli which may be present in the urinary tract
during urinary tract infections (UTI) can produce nitrous
oxide. However, the prevalence of high levels of nitrous oxide
in our sample of midwives is much higher than the
prevalence of UTI in women; furthermore, not all UTI is
caused by Gram negative bacilli. It is therefore unlikely that
UTI is the source of high baseline levels in urine prior to the
commencement of the shift.
Occupational exposure of midwives to nitrous oxide

oxide being present in the pre-shift sample, the possible reasons, including bioaccumulation with the potential for increased susceptibility to adverse effects, should be considered.

Quantification of the clearance of nitrous oxide from the body would permit personal occupational uptake to be measured by biological monitoring.

ACKNOWLEDGEMENTS
We would like to thank Mrs Brenda Rees and Mrs Anne Morgans, together with all the midwives who took part in this study. We would also like to thank Markes International for supplying the sampling tubes, and the Health and Safety Laboratory in Sheffield for the analysis of the personal environmental samples.
