To help inform the setting of dust control standards in coalmines, this brief review summarises the most recent and reliable exposure-response relations, for damaging respiratory effects, derived from the Pneumoconiosis Field Research (PFR). Collecting data over 38 years in the British coal industry, this was a programme of prospective research on the respiratory health of coal miners, characterised by regular health surveys and detailed measurements of dust and silica concentrations in the workplace. Exposure-response relations are presented for coal workers’ simple pneumoconiosis category II, progressive massive fibrosis, defined deficits of lung function (FEV₁), and category II silicosis. This simplified overview provides a guide to the most recent and most reliable estimates from the PFR of dust-related risks of substantial pulmonary disease, and to the magnitude of the effects. Control of dust sufficient to prevent category II simple pneumoconiosis should prevent most cases of progressive massive fibrosis and most dust related large lung function deficits. Where the dust contains high proportions of silica, control to low levels is essential, and even quite brief excursions of silica to high levels must be avoided.

The British Pneumoconiosis Field Research (PFR), a prospective exposure-response epidemiological study, was conducted by the Institute of Occupational Medicine, on behalf of the British coal industry, between 1953 and 1991. Supplementary studies and data analysis continue to this day. Its aim was “... to find out how much and what kinds of dust cause pneumoconiosis, and to establish what environmental conditions should be maintained if mine workers are not to be disabled by the dust they breathe ...”.

To inform setting and implementation of dust control limits, this review represents a brief summary of the most recent and most reliable estimates from the research of the quantitative dust related risks of damaging respiratory health effects. Supporting information on the research methods is given in the Appendix, and additional details may be found in the referenced source papers and reports.

METHODS
The PFR initially included 25, then 24, collieries, chosen to represent the range of conditions in British coal mines at the time. After the first 10 years of the research, 10 collieries continued in the study to 1977. Data collection continued in one colliery until 1980, with a follow up medical survey in 1991, because unusual airborne quartz concentrations were encountered.

Medical examinations were conducted on miners employed at these collieries every five years. A uniquely detailed prospective sampling strategy was implemented throughout the research, comprising measurements of respirable dust and quartz concentrations for numerous occupational groups in each colliery. Frequencies of measurements ranged from three monthly for surface workers up to 50 annually for high exposed groups. Concentrations were linked to occupational histories, in order to estimate a cumulative lifetime exposure for each man. Average concentrations, given as examples in this paper, are calculated by dividing cumulative exposure by total time worked.

OVERVIEW OF EXPOSURE-RESPONSE RELATIONS
Exposure-response relations have been established for the effects of mixed respirable coal mine dust on simple pneumoconiosis, complicated pneumoconiosis (progressive massive fibrosis), symptoms of chronic bronchitis, and clinically important lung function deficits, and for the effects of free crystalline silica on silicosis.

Simple pneumoconiosis and progressive massive fibrosis
The most reliable estimates of risks of coal workers’ simple pneumoconiosis (CWSP) and progressive massive fibrosis (PMF) were based on about 50 000 observations of men at risk during 25 years of the research. Methods are summarised in the Appendix. Risk of PMF is positively related to dust exposure, age, stature (tall for weight), the presence of CWSP, and the proportion of carbon in the coal. In this review risks have been expressed for coal that is 86.2% carbon, and the estimates have been adjusted for the estimated prevalence of CWSP.

Abbreviations: CWSP, coal workers’ simple pneumoconiosis; FEV₁, forced expiratory volume; PFR, Pneumoconiosis Field Research; PMF, progressive massive fibrosis
Figure 1 shows the risks at age 58 in comparison with average respirable dust concentration over a working lifetime of 40 years. Risks of an attack of PMF rise from about 0.8% at 1.5 mg.m$^{-3}$ to about 5% at 6 mg.m$^{-3}$. Risks of category II CWSP are higher, rising from about 1.5% at a mean concentration of 1.5 mg.m$^{-3}$ to about 9% at 6 mg.m$^{-3}$.

**Lung function**

The lung function of miners can be affected adversely by dust exposure, irrespective of the presence of pneumoconiosis. A study of 7000 miners defined clinically important deficits of forced expired volume in one second (FEV$_1$) by comparisons with reported symptoms of breathlessness, and then studied the dust related risk of having these deficits. A threefold increase in the odds of reporting “walking slower than other people on level ground because of their chest” was associated on average with a 0.993 litre FEV$_1$ deficit from predicted. This was defined as a clinically important lung function deficit, and is a substantial deficit by any standard.

Figure 1 illustrates the risks, for non-smokers and smokers, of having a deficit at least this magnitude at age 60 in relation to exposures to average dust concentrations experienced over a 35 year working life. For non-smokers, risks are about 10% for zero dust concentrations, rising to about 19% for an average concentration of 6 mg.m$^{-3}$. For smokers, risks were 22% and about 36% respectively.

The slope representing dust related increments in risk is similar to that for category II pneumoconiosis, so reductions in dust levels to protect against pneumoconiosis would protect a similar number of men from this lung function deficit.

Smaller deficits of lung function were also examined, showing steeper incremental slopes. For example, a twofold increase in risk of reporting breathlessness was associated with a 627 ml deficit of FEV$_1$. The risks of this deficit in non-smokers were about 25% at zero dust concentration, and nearly 40% at a mean concentration of 6 mg.m$^{-3}$. Comparable figures for smokers were 44% and nearly 60% respectively. A 1.5-fold increase in risk of reporting breathlessness was associated with a 367 ml deficit of FEV$_1$. The risks of this deficit in non-smokers were about 41% at zero dust concentration, and over 55% at a mean concentration of 6 mg.m$^{-3}$. Comparable figures for smokers were 62% and about 75% respectively.

**Silicosis**

In most British mines, free crystalline silica (quartz) concentrations in the dust are generally less than 10%, and quartz has no consistent influence on risks of pneumoconiosis after the effects of mixed dust have been taken into account. By contrast, in a few collieries, high quartz concentrations were associated with rapid progression of CWSP and the development of PMF. In one colliery in the research, adverse mining conditions resulted in unusually high quartz concentrations during the late 1960s and 1970s. Both the proportions of quartz in the respirable dust, and the absolute concentrations of quartz, were unusually high (sometimes over 20–30%, and with concentrations up to 2, 3, or 4 mg.m$^{-3}$ or higher). Subsequently cases of radiological abnormality developed with unusual frequency and rates of progression. Risks of radiological abnormalities 10 years after the colliery closed in 1981 were associated more strongly with exposure to quartz than to mixed dust, and the analyses indicated high risks at low concentrations.

In previous work, and in the results described so far in this paper, exposure has been expressed as concentration multiplied by time. This assumes that concentration has little influence on risk other than its contribution to cumulative exposure. It is plausible in the case of an agent like quartz that causes inflammation, and delays its own clearance from the lung, that high concentrations for limited periods might cause more damage than lower concentrations experienced over longer periods.

The fit was examined between different expressions of exposure and observed prevalence of radiographic abnormality. Methods are summarised in the Appendix. The exposure measure of best fit was the square of concentration multiplied by time. This is consistent with high concentrations causing disproportionately severe harm.

A good, simple, representation of the risks was given by a statistical model in which one exposure measure was confined to silica concentrations less than 2 mg.m$^{-3}$, and another to concentrations greater than 2 mg.m$^{-3}$. Figure 2 shows the risk estimates from this model, for category II silicosis. The risks for cumulative exposures to concentrations greater than 2 mg.m$^{-3}$ are very much higher than for exposures to concentrations less than 2 mg.m$^{-3}$.
Main messages

- Dust control sufficient to prevent simple pneumoconiosis category II should prevent most dust related large functional losses, and most cases of PMF.
- Where the dust contains high proportions of silica, control to low levels is essential, and even quite brief excursions of silica to high levels must be avoided.
- Risk estimates for these responses are given for a range of exposures.

Even a few months’ exposure to concentrations over 2 mg.m\(^{-3}\) results in a greatly increased risk; for example, four months’ exposure to 4 mg.m\(^{-3}\) gives a risk of 15%, and this risk would be greatly increased if chronic exposure to lower concentrations had also been experienced.

Clearly it is imperative that even quite brief excursions of quartz concentration to high levels are prevented.

Figure 3 shows the risks of silicosis compared with average concentrations, assuming all are in the low range, experienced over a 15 year period, with a 15 year subsequent follow up period. For example, risks are estimated to be 2.5% at an average concentration of 0.1 mg.m\(^{-3}\), rising to 20% at 0.3 mg.m\(^{-3}\).

The lowest exposure of any category II case was equivalent to a concentration averaged over 12 years of 0.1 mg.m\(^{-3}\). Below this, extrapolation indicated that at an average concentration of 0.02 mg.m\(^{-3}\), the risks are estimated at 1%, possibly not significantly different from zero (0.8% risk is estimated at zero exposure). Estimated risks reach 2% between 0.06 and 0.08 mg.m\(^{-3}\).

DISCUSSION

This simplified overview provides a guide to the most recent and most reliable estimates from the PFR of dust related risks of substantial pulmonary disease, and to the magnitude of the effects. Those seeking more detail, or who plan to use the information for dust control purposes, will wish to study the quoted sources, to grasp the breadth and complexity of the data.

Reliability of the risk estimates

PFR estimates of the risks of coal workers’ simple pneumoconiosis (CWSP) informed the setting of the current British statutory dust control limits that have been highly effective in reducing the incidence of pneumoconiosis.11

Men from all the British coalfields were included, representing a wide variety of mining conditions. The estimates of exposure are based on unusually detailed work history records and an unusually intensive long term programme of environmental sampling. Dust concentrations in the period before the research began (ISP0) (and for time spent at non-research collieries during the research) were assumed to have been the same as those measured in the first 10 years of the research. Should this have underestimated exposures, the resulting estimated exposure specific risks would have been exaggerated. This possibility cannot be completely excluded since the risks at low dust concentrations estimated from an earlier study14 that did not use ISP0 exposures were slightly lower than those estimated from a later study that did.2 The differences could have been influenced by different methodologies and further data quality improvements, though. Apart from this, these estimates are considered to overestimate very slightly the risks at low concentrations.

The risks of simple coalworkers’ pneumoconiosis and progressive massive fibrosis have been expressed for coal containing 86% carbon. Risks would be slightly higher for higher carbon proportions, and vice versa.2 1

The risks of silicosis described here are based on highly detailed exposure measurements, and are consequently reliable. If the effects of silica vary according to the conditions of exposure, these risks are probably towards the high end of the risk spectrum, since the silica was freshly fractured from massive sandstone, and not derived from dirt bands where the quartz grains are aged and accompanied by clay minerals.12

The reader will note that silicosis and PMF can appear or progress, and lung function continue to decline, after dust exposure has ceased. While our risk estimates are expressed for 58–60 year old men, these conditions may progress further during retirement. Note also that the silicosis risks are based on a 15 year period of exposure, and 15 year subsequent follow up. A longer period of follow up might identify further cases, though we would expect most of the eventual cases to have shown some signs of abnormality by now.

The estimated risks of lung function deficits fitted the observed data well.16 Some 10% of non-smokers at age 60 and with zero dust exposure are estimated to have a 993 ml deficit of FEV\(_1\). This includes any subjects with non-occupational disease (for example, asthma, past tuberculosis, bronchiectasis). For comparison, calculations from the quoted standard deviation in summary general population statistics16 indicate that about 2.5% of adult men have an FEV\(_1\) deficit of about 1 litre, not strongly influenced by age in healthy non-smokers.17 However, many of the studies on which these estimates are based excluded subjects with...
respiratory symptoms, thus presumably reducing the number of subjects with abnormal lung function.

While we have shown that brief exposures to high concentrations of silica have an important influence on risk of silicosis, this has not been examined in relation to the influence of mixed dust on pneumoconiosis or lung function. It would be interesting to do so.

ACKNOWLEDGEMENTS

We thank our many colleagues, past and present, who played important parts in this extended research programme; also the miners who took part, and the National Coal Board, subsequently British Coal, and the EU, HSE, and NIOSH, who funded the work.

APPENDIX

THE DESIGN OF THE PNEUMOCONIOSIS FIELD RESEARCH (PFR)

Structurally the PFR consisted of a series of cross-sectional studies of the respiratory health of currently employed (and in some studies ex-) miners, linked to a continuous and detailed prospective programme of measurements of dust exposure. Study of the data continues to provide answers to important questions, concerning coalminers and more generally.

Medical surveys

Six rounds of medical surveys, at approximately five yearly intervals, were conducted between 1953 and 1977. Of the 25 pits included in the first round (PFR1, from 1953 to 1958), 24 were included again in PFR2 (1957 to 1963), and PFR3 (1963 to 1968; end of first phase). For PFR4 (1970 to 1973) and PFR5 (1973 to 1977), the number of collieries was reduced to 10 (second phase). Two collieries were included in PFR6 in 1977, after which the regular surveys stopped. Data collection (including medical surveys in 1978 and 1991) continued in one colliery where unusual quartz concentrations had occurred.

Work histories

The men at each colliery were allocated to occupational groups based on place of work and occupation, revised as mining conditions and practice changed. Weekly records for every man in the occupational groups were supplemented by medical survey interviews on other coalmining experience.

At the colliery with unusual quartz concentrations, time worked was recorded as hours within each occupational group, from 1954 until closure in 1981, but in much more detail after 1974.

Dust measurements

Dust concentrations were monitored using sampling instruments close to individual men (“instrument carriers”) throughout selected working shifts. On this basis the average concentrations of respirable coalmine dust were determined for all occupational groups and every five year inter-medical survey period (ISP1, 2, 3, 4, and 5). The standard thermal precipitator was used in the first phase of the research. Its dust sampling characteristics were related, during a series of side-by-side instrument comparisons to those of the MRE gravimetric sampler that was used subsequently. The earlier particle count measurements were re-expressed in equivalent gravimetric units. It was assumed that dust concentrations before the research began (ISP0) were similar to those experienced during the following 10 years.

Respirable dust samples were pooled within occupational groups to enable measurement of the quartz content. In the colliery with unusual quartz concentrations, quarterly mean quartz concentrations were available for each occupational group from 1968.

Dust exposures

The exposures of individuals to respirable coalmine dust in any ISP were calculated by forming the products of hours worked (in occupational groups) with the corresponding average dust concentrations, and summing these products over all groups in which the man had worked over the period.

Medical examinations

At each examination a full sized postero-anterior chest radiograph was taken. They were read for clinical purposes for the studies reported here during the first phase of the research by at least two of four medical officers experienced in the classification of the appearances of pneumoconiosis. Subsequent radiographs were interpreted by any one of five or six medical officers. Radiographs for the study of silicosis were read in a special reading trial by a panel of three expert medical readers according to ILO 1980.
breathlessness. The selected values were factors of 1.5, 2, and 3, and the associated FEV₁ deficits were found to be −0.367, −0.627, and −0.993 liters respectively.

Secondly, the association between FEV₁ and exposure to respirable dust up to PFR5, adjusted for age, physique, and smoking habit, was examined by multiple linear regression, and this model was used to calculate the estimated values of FEV₁ associated with various levels of cumulative dust exposure. Separate estimated values were calculated for different age and smoking groups as necessary. Assuming that the distribution of levels around this estimate followed a Normal distribution, it was possible to estimate the probability that any individual would have an FEV₁ below any specified value, including the three values derived from the earlier analyses.

Silicosis

The analysis was based on 549 men who attended the 1991 follow up survey at this colliery, out of a study population of 1416 who had attended at least one of the surveys in 1970, 1974, and 1978.

A series of general exposure indices (GEI) to quartz were derived with parameters that described the influence of lung residence time and “peakness” of exposures. Each GEI was formed by the sum of the products of time, concentration, and elapsed time since exposure for each occupational group, with concentration and elapsed time raised to different powers for each GEI.

The strength of statistical associations between the profusion of small opacities at follow up survey and a series of candidate GEIs were compared, using polychotomous logistic regression models. The indices for concentration were highly significant within both the <50 and 50–75 age groups, with the largest deviances in the latter group. In the <50 group, deviations for GEIs with a power of concentration less than 1 were highest, whereas for the 50–75 group powers greater than 1 gave the highest deviances, the highest being the square of the concentration. In the 75+ group, however, GEI estimated effects were very low and non-significant. In all age groups little influence of elapsed time was shown, probably because there was a narrow range of times, since men had tended to experience their high exposures, and were followed up, at similar calendar times.

The form of the above statistical model is inconvenient for predictions of risk based on hypothetical exposures. An alternative model comprising only two explanatory quartz concentrations, and showed the strongest exposure-response relations.

To enable the summary comparisons in this paper, risk estimates have been derived from the summary data presented in the source papers either directly or with a cautious degree of approximation or extrapolation. The estimates are in some cases expressed in relation to slightly different limits of age and working lifetime. The authors of the source papers made these choices based on the characteristics of the populations and information requirements at the time. We have not attempted to rework the estimates for greater consistency, but suggest that these relatively trivial differences can be ignored for the purposes of this overview.
