Asymptomatic sensitisation to grapes in a sample of workers in the wine industry

Aims: To assess the prevalence of sensitisation to grapes (Vitis vinifera var. agiorghitiko) in a population with repeated exposure to grape allergens through direct cutaneous contact as well as through the gastrointestinal tract.

Methods: One hundred and twenty subjects were enrolled in each of four groups: grape harvesters, winery workers in selection of grapes, winery workers operating de-stemming/crushing/pressing machines, and administrative personnel. Sensitisation to grapes was examined by skin prick-to-prick tests with fresh fruit and juice.

Results: Eight harvesters and five workers in grape selection had positive reaction to the grapes tested. No machine operators or administrative personnel had positive tests. The likelihood of sensitisation was estimated at 3.7% per year of occupation by logistic regression analysis. None of the employees reported symptoms associated with sensitisation to grapes.

Conclusion: Asymptomatic sensitisation to grapes was detected only in workers handling the fruit, suggesting that sensitisation is more likely to occur through cutaneous exposure and/or minor wounding than through the gastrointestinal tract. Prevalence rates were high and the clinical impact needs to be further investigated.

Grapes (Vitis vinifera, Vitis labrusca) are extensively cultivated plants in temperate regions for consumption and the production of wine. Despite widespread consumption since prehistorical times, as suggested by the popular worship of deities such as Dionysus and Bacchus and consequent exposure of a large part of the general population to grape allergens, allergy to grapes is relatively rare. Allergic reactions to grapes reported in the literature are limited and described mainly as case reports. A recent study identified endochitinase 4, a lipid transfer protein and a thaumatin in the grape allergens in V vinifera and V labrusca species, but whether these allergens are the only ones in all lesser/hybrid grape species has not been properly investigated. The prevalence of sensitisation to grape species and varieties is still undetermined.

Repeated exposure to an allergen increases the chance of sensitisation. This fact has been confirmed by numerous studies reporting increased sensitisation after long term exposure, including increased sensitisation to hymenoptera venom in beekeepers, to latex in hospital personnel, and to laboratory animals’ allergens in laboratory workers. The aim of this study was to assess the prevalence of sensitisation to grapes, in a population with repeated exposure to grape allergens through direct cutaneous contact as well as through the gastrointestinal tract.

Subjects and Methods

Subjects worked at the vineyards and “K Bourtas” winery of Nemea, a red wine producing area of North Peloponnesos in Greece. Grapes cultivated in the Nemea region are of the Vitis vinifera species, agiorghitiko variety that is native to the region.

One hundred and twenty subjects were enrolled in each of three groups—harvesters (group A), workers in grape selection (group B), and workers operating de-stemming/crushing/pressing machines (group C) after consent was obtained from the vineyard owners and the management of the winery. One hundred and twenty healthy office employees in the region were included in the study as controls (group D). There were no refusals and informed written consent was obtained from all individuals selected. Harvesters worked in the vineyards for 10 hours daily for 20–30 days each year, gathering the fruits in containers with bare hands. Workers in selection of grapes sorted out with bare hands different quality grapes passing in front of them on conveyor belts. Participants in the grape selection worker group were all women. Workers operating the de-stemming/crushing/pressing machines did not come in direct contact with grapes or their products, but inhaled de-juiced must vapours for eight hours daily. All administrative personnel in the control group worked in different buildings and had no contact with grapes or grape products. Most of the subjects consumed grapes regularly during working hours (particularly in groups A and B) and at home.

All workers completed a short questionnaire regarding their sociodemographic characteristics as well as history and family history of atopic diseases diagnosed by a doctor (asthma, rhinitis, urticaria, food and drug allergy, and atopic dermatitis). Reported symptoms of oral allergy syndrome, contact urticaria, or anaphylaxis after grape consumption were also recorded. Cumulative duration of occupation was estimated, as working in vineyard harvesting-winery jobs is a one month per year seasonal occupation.

Skin prick-to-prick tests were performed on all employees with grapes and grape juice in the following manner: a single use standard prick needle was inserted into the grape and then immediately into the skin. Prick-to-prick tests with fresh fruit are considered to be more reliable in diagnosis of grape sensitisation compared to the commercial skin tests, particularly if a specific species is to be investigated. Grapes were tested after their surface was cleaned with absolute ethanol to rule out possible fungal contamination. A positive skin reaction was defined as the presence of a wheal equal to or greater than the one elicited by a histamine hydrochloride (10 mg/ml) control after 20 minutes. Normal saline was used as negative control. Results were recorded in transparent tape and erythema and wheel surface was estimated through the use of a planimeter. None of the subjects reported intake of any drugs that interfere with skin reactivity (antihistamines, sedatives, etc). Recent studies have shown a possible relation between allergic reactions to grapes and other fruits.
Sensitisation to apple, peach, cherry, and banana was also investigated using prick-to-prick tests. Investigation of atopy using skin prick tests with 10 commercial allergens was not possible on all employees due to the production schedule of the winery. Blood samples were not drawn from the workers for radioallergosorbent test (RAST) and total IgE measurement for the same reasons.

Odds ratios and 95% confidence intervals were calculated only between groups presenting positive skin tests. A classical model of logistic regression analysis (forward stepwise) was applied to explore the association between grape sensitisation and the following variables: age (in years), sex (male = 0, female = 1), personal history of atopic diseases (no = 0, yes = 1), family history of atopic diseases (no = 0, yes = 1), and total time interval in workplace (in months). The Statistical Package for the Social Sciences (SPSS) was used for the statistical analysis.

RESULTS

Table 1 presents demographic data for the employees. None of the participants reported symptoms of anaphylaxis, contact urticaria, or oral allergy syndrome to grapes.

Eight workers in group A (6.7%) and five (4.2%) in group B presented positive prick-to-prick tests to grapes. Differentiation in sensitisation in the two groups is not significant as shown by the calculated odds ratio of 1.64 (95% CI 0.52 to 5.17). None of the workers in groups C or D presented positive tests to these fruits. Although we did not perform RAST inhibition tests, the distribution of sensitised workers to these fruits in association with their reactivity to grapes suggests that grape sensitisation in the groups under study is not likely to be the result of cross-reaction.

Results of logistic regression analysis performed on employees of groups A and B in order to investigate the possible association of certain variables on sensitisation to grapes indicate that only the duration of occupational exposure can be considered a determinant. For each year of occupation in harvest or winery jobs the risk of sensitisation to grapes increases by 3.7% (table 1).

DISCUSSION

In this study we set out to investigate the prevalence of sensitisation to *Vitis vinifera* in a population with increased exposure through direct cutaneous contact as well as through the gastrointestinal tract. Results indicate that in subgroups A and B, where the exposure was greater, the prevalence of sensitisation was 6.7% and 4.2% respectively. Since there are no relevant studies on grapes, comparative analysis is not
possible. Prevalence of sensitisation to other products in workers in respective manufacturing industries indicates similar results. Sensitisation to enzymes in the animal feed industry has been estimated to be 7%.\textsuperscript{9} Sensitisation to latex, a high potency allergen, in tappers and glove factory manufacture workers has been reported to range between 1.3% and 11% in four studies.\textsuperscript{10}

The reported sensitisation to grapes in the population studied is asymptomatic since none of the employees reported history of symptoms associated with anaphylaxis, contact urticaria, or oral allergy syndrome after grape consumption. Although the hypothesis that workers sensitised with work related symptoms might have been forced to leave the exposure cannot be ruled out, the fact that none of the workers under study was symptomatic suggests that this possibility is remote. The clinical impact of sensitisation cannot be assessed without further investigation. We informed in writing all sensitised individuals and counselled them in case of symptom presentation. We intend to repeat testing after three years.

Sensitisation to grapes was detected only in workers handling the fruit, suggesting that sensitisation is more likely to occur through cutaneous exposure and/or minor wounding than through the gastrointestinal tract. Results of the logistic regression analysis tend to confirm this hypothesis, since the only variable increasing the likelihood of sensitisation is increased duration of occupational exposure. This likelihood has been estimated to be 3.7% for each year of occupation. Unfortunately it was not possible to investigate atopy predisposition by prick tests in all workers. However, no association between history and family history of atopic diseases and sensitisation to grapes was established with the logistic regression analysis.

This is the first study attempting to estimate the prevalence of sensitisation to grapes in grape harvesters and workers in wineries. Further investigations should be undertaken to confirm the results and provide more data on this issue.

**ACKNOWLEDGEMENTS**

We thank all workers in Nemea vineyards and the “K Boutaris” winery who participated in this study, and the “K Boutaris” company for financial support.
