Heat-related and cold-related deaths in England and Wales: who is at risk?

S Hajat, R S Kovats, K Lachowycz

Background: Despite the high burden from exposure to both hot and cold weather each year in England and Wales, there has been relatively little investigation on who is most at risk, resulting in uncertainties in informing government interventions.

Objective: To determine the subgroups of the population that are most vulnerable to heat-related and cold-related mortality.

Methods: Ecological time-series study of daily mortality in all regions of England and Wales between 1993 and 2003, with postcode linkage of individual deaths to a UK database of all care and nursing homes, and 2001 UK census small-area indicators.

Results: A risk of mortality was observed for both heat and cold exposure in all regions, with the strongest heat effects in London and strongest cold effects in the Eastern region. For all regions, a mean relative risk of 1.03 (95% confidence interval (CI) 1.02 to 1.03) was estimated per degree increase above the heat threshold, defined as the 95th centile of the temperature distribution in each region, and 1.06 (95% CI 1.05 to 1.06) per degree decrease below the cold threshold (set at the 5th centile). Elderly people, particularly those in nursing and care homes, were most vulnerable. The greatest risk of heat mortality was observed for respiratory and external causes, and in women, which remained after control for age. Vulnerability to either heat or cold was not modified by deprivation, except in rural populations where cold effects were slightly stronger in more deprived areas.

Conclusions: Interventions to reduce vulnerability to both hot and cold weather should target all elderly people. Specific interventions should also be developed for people in nursing and care homes as heat illness is easily preventable.
database of care and nursing homes in the UK to determine whether individuals had been residents of care or nursing homes at the time of death. This database was obtained from a market intelligence company (http://www.laingbuisson.co.uk) and included information on every care and nursing home in the UK (including local authority homes) registered in 2003. Most records are fully postcoded, except for a few small registered homes where local authority records are incomplete. Non-linked deaths were assumed to be from non-care-home settings.

Postcode information on the death certificate was used to link the deaths to census output areas, which have an average population size of 300 residents and are the smallest geographical areas for which detailed 2001 UK census results are available. The urban and rural classification was used to classify the output area as urban (where the majority of the population size of 300 residents and are the smallest geographical areas for which detailed 2001 UK census results are available. The urban and rural classification 2004 was used to classify the output area as urban (where the majority of the population lives in urban areas, with more populous wards in large urban areas. Each death was also linked at the census area statistic ward level to the following 2001 census variables that may modify temperature effects: proportion of all people aged >65 years who are living alone; proportion of all people living in a flat, maisonette or an apartment; proportion of all people of all ages who describe themselves as Asian; and proportion of all people of all ages who describe themselves as black. Wards are subdivisions of local authorities with an approximate national average of 5500 people, but with more populous wards occurring in large urban areas.

To allocate an area-level measure of deprivation, the postcodes were linked to indices of multiple deprivation for England and Wales. These are composite scores based on a range of indicators using a mixture of census data and other routinely available indicators across several domains of deprivation, such as employment, income, housing and health. The underlying indicators and construction of the index are different between England and Wales, and therefore deprivation was considered separately in each country. To be consistent with the census data linkage, the scores which are available at the Super Output Area (groups of output areas) were summarised into a population-weighted average at the census area statistic ward level.

These data were then collapsed into a count of total mortality for each day during the 11-year study period. Counts were subdivided by region, sex, age group (0–64, 65–74, 75–84, >85 years), cause of death (cardiovascular, respiratory, external or other), urban or rural, long-term care status (care home, nursing home or none), and region-specific quintiles of the census and deprivation variables.

### Data on weather, air pollution and influenza

Daily maximum and minimum temperature data (°C) for 1993–2003 were obtained from the Central England Temperature series, a weighted mean temperature indicator for Central England. In addition, for all regional analyses, the same data were collected from one site representative of each region from the British Atmospheric Data Centre (table 2). Daily mean temperature for each series was created by taking the mean of the daily maximum and daily minimum values.

The short-term relationship between temperature and mortality may be confounded by air pollution levels and influenza epidemics. Therefore, daily ambient levels of PM10 and ozone (µg/m³) were collected from the National Air Quality Monitoring Network, London, UK. One monitoring site in each region for each pollutant that provided most non-missing data was deemed sufficient to provide a measure of temporal change. For the regions in England, weekly reports of laboratory-confirmed influenza A and influenza B activity were also collected from the Centre of Infection, Health Protection Agency, London, UK.

### Statistical analysis

Each daily mortality series was examined in relation to daily temperature using Poisson generalised linear models allowing for overdispersion. Cubic smoothing splines of time with equally spaced knots were used to control for secular trends in the mortality series and any additional confounding by seasonally varying factors other than temperature. Seven degrees of freedom (df) per year for these smoothing splines was deemed sufficient to provide a measure of temporal change. For the regions in England, weekly reports of laboratory-confirmed influenza A and influenza B activity were also collected from the Centre of Infection, Health Protection Agency, London, UK.

For quantification of temperature effects, simple linear threshold models were assumed—that is, models which...
assume a log-linear increase in risk above a heat threshold and below a cold threshold. To estimate temperature effects relative to regional climates, the heat threshold was derived from the 95th centile of mean temperature (average of lags 0–1) and the cold threshold (average of lags 0–13) from the 5th centile for each region separately. Linear heat and cold effects were estimated simultaneously. As a sensitivity analysis, effects for cold were also estimated using the summation of lags 0–13 when each of these lags was entered separately into the regression model—namely, an unconstrained distributed lag model. However, results using this approach were largely unchanged.

All analyses were repeated separately for each region. Region-specific estimates of heat and cold effects were pooled across regions in a fixed-effects meta-regression to provide mean estimates.

As temperature-related risk factors may be modified by place of death, all analyses were repeated on just those deaths occurring at home. All analyses were conducted using Stata V.9.

### RESULTS

Table 3 shows summary statistics of the daily mortality and temperature data. The more elderly population of the East and South of England are reflected in a higher percentage of deaths in the ≥85 years of age group in these regions. The percentage of deaths in males for the whole of England and Wales (not shown in the table) was 47.8% and the percentage of deaths due to cardiovascular disease (CVD), respiratory disease and other causes was 41.0%, 15.5% and 2.9%, respectively. There were few regional departures from these distributions except that there was a slightly lower percentage of male deaths in southeast England, a slightly higher percentage of deaths due to respiratory disease in London, more deaths due to CVD in Wales and more deaths due to CVD and less deaths due to respiratory disease in southwest England.

Mean summer temperatures were highest in the southern regions, with London having particularly high levels, and mild wintertime temperatures were observed in Wales and the South West due to the Gulf Stream.

![Table 3](https://www.occ envmed.com)
Temperature–mortality relationships

Figure 1 shows the relationship of the relative risk (RR) of death (all regions) with daily mean temperature from the Central England Temperature series, subdivided by age and cause. Graphs A and B show the relationship with temperature averaged across lags 0–1 to model the heat effect, and graphs C and D show temperature averaged across lags 0–13 to model the cold effect.

In general, effects for both heat and cold were stronger in the more elderly age groups. Heat effects seemed to begin once mean temperature reached a value of 17–18 °C and cold effects were strongest once temperatures fell below about 5 °C. The relationship of death with both heat and cold seemed fairly linear above and below the threshold points.

An increase in deaths was associated with high temperatures in all cause-of-death groups; however, effects were strongest for respiratory disease and deaths from external causes. With longer lags of temperature, risks were particularly strong for low temperature and those with respiratory disease. When repeating this analysis by age group (not shown), heat effects were strong in those with respiratory disease only for the ≥85 years age group, whereas for the 0–64 year age group the strongest heat effect was on external causes. Both respiratory and external causes were strongly associated with cold in the ≥85 years age group, but only respiratory deaths were cold related in the 0–64-year olds.

Figure 2 shows the temperature relationships by sex and rurality. Heat effects were stronger in females than males, but little modification of the cold effect was observed by sex. Similarly, a stronger heat effect was observed for those people living in urban areas, but no differences were observed for cold.

Figure 3 shows the temperature relationships by long-term care status. A stronger effect for both heat and cold exposure was observed in deaths in nursing homes than those in care homes, which in turn was stronger than for non-residential home deaths. This differential remained for heat exposure when analysis was restricted to the ≥85 years age group; in the case of cold weather, however, all groups now seemed equally vulnerable (data not shown).

Regional estimates

All the above relationships were largely unchanged when analyses were repeated for individual regions, although a stronger cold effect in rural settings was apparent in the regions of the North and the Midlands.

Figure 4 shows for each region the RR of total mortality associated with a 1 °C change in temperature above and below region-specific heat and cold thresholds. Also shown is a mean effect estimated from a fixed-effect meta-analysis, giving a RR of 1.03 (95% confidence interval (CI) 1.02 to 1.03) for each degree increase in high temperature, and twice that for the cold effect: RR 1.06 (95% CI 1.05 to 1.06). Heat effects were
strongest in London compared with other regions. Cold effects seemed particularly strong in the East of England; however, the amount of data available for this time series was much reduced because of missing pollution data. When pollution was not controlled for, and the full 11 years of deaths were analysed, the cold estimate for the East region was more in line with the other regional estimates: RR 1.06 (95% CI 1.05 to 1.07).

Figure 5 shows the mean estimate per degree change by sex and age groups. The heat effect was greater in women than in men for all age groups >65 years, and the differences become larger with increasing age. Cold effects were not modified by sex within each age group.

Deprivation and census variables

Very little modification was observed by quintiles of deprivation for either the heat or cold effect in any of the 10 regions studied. Figure 6 shows the mean estimate for each level of deprivation separately for urban and rural settings. As before, the heat effect was stronger in urban locations than in rural settings. However, there was very little pattern across quintiles of deprivation. The notable exception to this was for cold exposure in rural areas where a stronger effect seemed to be in evidence for increasingly deprived groups, but conventional levels of significance were not reached in a test for trend because of the wide CIs in the individual estimates.

There was little evidence of modification of either the heat or cold effect by quintiles of the proportion of people living in flats, the proportion of elderly (aged >65 years) people living alone or the proportion of ethnic minority groups (not shown).

Restriction of all analyses to only those deaths occurring at home (20.0% of all deaths) did not substantially alter any of the temperature relationships except that a heat effect in rural communities was no longer apparent.

DISCUSSION

Our results confirm that elderly people are most at risk from temperature-related mortality, but within this group there are important determinants of risk. Women aged ≥65 years seem to be at increased risk of heat-related mortality. There may be an adverse effect of menopause on thermoregulation, in addition to its effects on cardiovascular fitness. Other studies have also shown greater vulnerability to heat in women.\(^\text{19, 44}\) Important social factors may explain differences in mortality patterns between men and women during heat waves. For example, in Paris, the heat risk increased for unmarried men but not for unmarried women, and being a foreign national benefited women but not men.\(^\text{45}\) Macey and Schneider\(^\text{44}\) found stronger cold effects in men, whereas Wilkinson\(^\text{16}\) et al reported an increased cold risk in women. We observed little modification of the cold effect by sex.

Clear regional differences were observed in the temperature–mortality relationships, with London residents being particularly vulnerable to heat effects. Cold exposure seemed particularly strong in the East region of England; however, the estimate was much reduced when years with missing pollution data were also included in the analysis. Previous work has also hinted at stronger cold effects in the East region,

...
which may be partly explained by a relatively old population and also by exposure to cold winds. Although the importance of wind chill has been shown,\textsuperscript{47, 48} wind chill was not found to be a better predictor of mortality than temperature alone.\textsuperscript{49} Additional analysis (not shown) of our East region data showed that mean wind speed (measured in knots) did not predict mortality in our models, but wind direction did slightly (measured as north, south, east or west derived from degrees true). Only wind direction on the same day as the day of death was predictive, and no interactions between wind direction and cold temperature were observed. Also, estimates for both heat and cold remained unchanged when relative humidity (%) was controlled for.

When analysing by cause, we observed that deaths from respiratory and external causes were most strongly associated with hot weather, although it should be remembered that these two groups accounted for only 18.4% of all deaths in England and Wales during the study period. Although weather and health studies rarely consider effects on deaths from external causes, our results suggest a strong heat signal from such causes in the 0–64 years age group. Such deaths are unlikely to be explained by short-term forward displacement of already vulnerable people (“harvesting”), and so represent substantial shortening of lives.\textsuperscript{50} Other studies have reported increases in hospital attendance for injuries in young children on dry and sunny days.\textsuperscript{51, 52} Few deaths are categorised as heat stroke being shortening of lives.\textsuperscript{50} Other studies have reported increases in hospital attendance for injuries in young children on dry and sunny days.\textsuperscript{51, 52} Few deaths are categorised as heat stroke being

As with many other studies, we found no relationship of cold with deprivation.\textsuperscript{11–17} Previous work has shown that people in lower socioeconomic groups do not necessarily live in cooler homes, as housing association and local authority dwellings tend to be well heated,\textsuperscript{4} whereas large owner-occupied houses may, on the other hand, be more difficult to heat. Reliance on poor public transport systems may increase exposure to outdoor cold, particularly in more rural areas.\textsuperscript{57} Lawlor et al\textsuperscript{58} observed no association between excess winter mortality and rurality in one region of England, whereas Macey and Schneider\textsuperscript{44} reported a greater risk in rural areas. Our results suggest an increased risk in rural populations only in certain regions of England, but perhaps more importantly, we observed that within these rural populations, cold effects may indeed be stronger in more deprived areas.

Heat effects were observed to be particularly severe in urban areas. This is probably due to the heat-island effect whereby greater heat retention occurs in more heavily built-up areas.\textsuperscript{59–60} In contrast with studies from the US,\textsuperscript{22–25} we observed no modification of the heat effect by deprivation. This difference is likely to be due to the fact that lower social class in the US will, to a large extent, reflect lack of ownership of home air-conditioning units, whereas in the UK, at least at present, few households have such systems.

However, the lack of modification of either the heat or cold effect by quintiles of deprivation may also reflect the fact that area-level markers are being used to represent individual circumstances. Other variables measured at the electoral ward level, such as living arrangement and ethnicity, also seemed to show no modification of temperature effects.

By analysing deaths for the whole of England and Wales, individual-level differences in the heat and cold effect within subgroups of the population could be accurately estimated. In particular, by linking the individual mortality files to the postcoded database of care homes, we could uniquely identify whether each death occurred in care, nursing or home residents. Smaller care homes may not have had unique postcodes and there may have been some de-registering of care homes over the study period; however, such misclassification would only serve to reduce any temperature differentials.

In conclusion, our results provide evidence of differences across the population of risk to temperature-related mortality. Public health initiatives to combat the dangers of ambient temperatures should be targeted to elderly people and residents.
Main messages

- The effects of both heat and cold on mortality are apparent throughout the elderly population, but those living in nursing and residential homes are at highest risk.
- Children and adults (aged 0–64 years) were also affected by heat from deaths from external causes.
- Vulnerability to either the heat or cold was not modified by deprivation, except in rural populations where cold effects were slightly stronger in more deprived areas.
- There were few regional differences, except that heat effects were particularly strong in London and cold effects were possibly stronger in the East of England.

Policy implications

- Improvements in care and the indoor environment (such as better staff training and the installation of space conditioning) are needed to reduce vulnerability in nursing and care homes.

in long-stay care who are particularly vulnerable to both hot and cold weather.

ACKNOWLEDGEMENTS

We thank the Office for National Statistics, London, UK, for supplying the data on mortality.

Respiratory symptoms and damp housing

People living in damp housing have a higher prevalence of respiratory symptoms and asthma, a study has confirmed. The Respiratory Health in Northern Europe (RHINE) is a follow-up study of 16,190 subjects from Iceland, Norway, Sweden, Denmark, and Estonia who participated in the European Respiratory Survey stage 1 in 1990-4. The mean age of the subjects was 40 years and 53% were women. This is the largest study to have addressed the effects of dampness in the home on respiratory symptoms in adults.

Exposure to indoor dampness was considered if, in the past 12 months, there had been water leakage, bubbles or discoloration on floors or visible mould growth on walls, floor, or ceilings.

Respiratory symptoms were defined as wheezing in the chest; being woken by an attack of shortness of breath or attack of coughing; usually bringing up phlegm or having problems bringing up phlegm. All three indicators of indoor dampness were significant risk factors for every respiratory symptom. The strongest associations were found between dampness in floor material and all respiratory symptoms and asthma. Water damage was not found to be a significant risk factor for asthma.

Living in a dry house facilitates remission of nocturnal respiratory symptoms since remission was less likely in damp homes. The relation between building dampness and respiratory symptoms shows that it is important to reduce indoor dampness by improved housing construction, better indoor ventilation, and effective repairs of water leaks.
