The prevalence of mental health disorders in (ex-)military personnel with a physical impairment: a systematic review

S A M Stevelink,1 E M Malcolm,1 C Mason,1 S Jenkins,1 J Sundin,2 N T Fear1,2

ABSTRACT
Background Having a visual, hearing or physical impairment (defined as problems in body function or structure) may adversely influence the mental well-being of military personnel. This paper reviews the existing literature regarding the prevalence of mental health problems among (ex-)military personnel who have a permanent, predominantly, physical impairment.

Results 25 papers were included in the review, representing 17 studies. Studies conducted among US military personnel (n=8) were most represented. A range of mental health disorders were investigated; predominately post-traumatic stress disorder (PTSD), but also depression, anxiety disorder (excluding PTSD), psychological distress and alcohol misuse. The findings indicate that mental health disorders including PTSD (range 2–59%), anxiety (range 16.1–35.5%), depression (range 9.7–46.4%) and psychological distress (range 13.4–36%) are frequently found whereby alcohol misuse was least common (range 2.2–26.2%).

Conclusions Common mental health disorders were frequently identified among (ex-)military personnel with a physical impairment. Adequate care and support is necessary during the impairment adaptation process to facilitate the psychosocial challenges (ex-)military personnel with an impairment face. Future research should be directed into factors impacting on the mental well-being of (ex-)military personnel with an impairment, how prevalence rates vary across impairment types and to identify and act on specific needs for care and support.

BACKGROUND
In the past decade, the proportion of military personnel who died during a conflict decreased due to technological and medical progression, including protective gear and equipment, the rapid removal of severely injured personnel from the battlefield and increased use of military tourniquets.1–4 Consequently, combat-related morbidity among those returning from conflicts increased.5–3 Furthermore, it has been posited that military personnel who have served in the conflicts in Iraq or Afghanistan are more likely to sustain particular impairments than personnel who have served in other conflicts as a result of the increased use of improvised explosive devices.5–8 Wounds to the extremities are common, which may result in amputations.8 Besides amputations, other impairments are reported including vision or hearing loss and head injury.10

Recent studies assessed the mental well-being of the US and UK troops that have been deployed to Iraq and Afghanistan, suggesting that the rates of mental health problems vary but are substantial.11–13 We know that combat-related trauma experienced while on deployment is a risk factor for mental or physical health problems.11 14 15 Studies among military personnel from the US, UK and Israel suggest that, compared to uninjured personnel, those injured during deployment have significantly higher rates of post-traumatic stress disorder (PTSD).14–17 Wounded or injured US soldiers were also more likely to misuse alcohol or be diagnosed with any mental health disorders (eg, PTSD, anxiety, mood, adjustment, substance abuse).17 18 However, no increased prevalence of mental health disorders other than PTSD was identified among the UK sample.14 Furthermore, the physical and psychological issues of adapting to a life with an impairment may affect the well-being of the person.19–24

This paper reviews the prevalence of mental health disorders among, mainly physically, permanently impaired (ex-)military personnel.

METHODS

A total of 2946 papers were identified during the initial searches. Papers were included if they: (1) comprised data on (ex-)military personnel with a physical, visual or hearing impairment, (2) administered at least one validated outcome measure of mental health or participants self-reported to have a mental health problem, or hospital records/military databases indicated the presence of a mental health problem, and (3) were reported in English.

In the current review, impairment was defined as ‘problems in body function or structure such as
significant deviation or loss." We used the terms visual and hearing impairment to refer to problems with vision and hearing, respectively, whereas a physical impairment included problems with extremities, mobility, spinal cord injury or missing limbs. A permanent impairment suggests an impairment that supposedly will not improve and remains for life including amputations, irreversible vision and hearing loss. It was not possible to use more stringent criteria for the different types of impairment as often limited detail about the impairment was provided in the studies published. We aimed to review studies including a variety of impairment types. However, the majority of the studies identified focused on physically impaired participants; this is therefore the main focus of the current review paper. The term (ex-)military personnel included those currently serving in the Armed Forces and those who had now left the Forces and returned to civilian life (often referred to as veterans).

After a first selection by SAMS, based on title and abstract, the remaining 112 papers were read in full by SAMS and EMM and assessed for inclusion in the review. Any discrepancies were discussed. Also the bibliographies of the selected papers were scanned for eligible studies.

A quality scoring methodology was used to critically appraise the studies included. This methodology was derived from a framework for critical appraisal. The quality score was calculated based on five criteria with a highest possible score of 5 and 0 as the lowest possible score. A high score indicated a better quality study. The criteria included: (1) clear statement of aims/description of target population: yes (score 1), no (score 0); (2) sample: random sampling (score 1), non-random sampling for example, opportunity or self-selected (score 0); (3) sample size >1000 (score 1), <1000 (score 0); (4) response rate/follow-up rate >60% (score 1), <60% or not stated (score 0); (5) use of standardised/validated measures yes (score 1), no (score 0). The studies were independently appraised by CM and SJ and the results compared. Any discrepancies were discussed with SS and a consensus was reached. Final quality scores are shown in online supplementary table S2.

Forest plots were created to provide an overview of the prevalence estimations from the different studies per mental health disorder. This was carried out using the Forest Plot Viewer Graphing Tool. The different impairment groups identified in the various studies and the few studies that included a control group are represented in the forest plots. Reference lines have been added in the forest plots at baseline (0%) and first quartile (25%) to guide the reader.

RESULTS
A total of 2946 papers were identified during the initial searches. After removing the duplicates, 2352 papers were screened. Based on title and abstract, 2240 papers were excluded and 112 full-text papers were assessed (figure 1). Twenty-five papers were included in the review, based on 17 different studies (see table 1). Eight studies were based on a sample of US (ex-)military personnel, and five studies were conducted in Sri Lanka (3), Croatia (2), Iran (1), Korea (1), Nicaragua (1) and the UK (1). The design of the studies varied. Seven cross-sectional surveys were identified, two studies focused solely on hearing impairments, and three studies included participants with a range of impairments, including physical, visual and hearing impairment.

The majority of the studies involved (ex-)military personnel with a physical impairment, such as an extremity amputation or spinal cord injury. Two studies focused on hearing impairments and three studies included participants with a range of impairments, including physical, visual and hearing impairment. The majority of the studies investigated the prevalence of PTSD (n=13), anxiety (n=5), followed by depression (n=9), substance misuse (n=5) and psychological distress (n=3). The majority of the papers received a quality score of 2 (n=14), followed by a quality score of 3 (n=9) and 1 (n=2) (see online supplementary table S2).

Post-traumatic stress disorder
Overall, the prevalence of PTSD was highest in a study of US military personnel with different types of amputations that returned from deployment in Iraq or Afghanistan; 59%

reported suffering from PTSD (total sample size n=283). The lowest prevalence of PTSD was identified among quadriplegic US military personnel (2%; n=52). In a study of 89 Croatian soldiers, those with non-disabling injuries had a higher prevalence of PTSD, 52.9% (n=29), followed by those with a permanent disabling injury (at least one extremity amputation) (29.4%; n=30) and soldiers who were still actively serving (17.7%; n=30).

The only study that examined the prevalence of PTSD among soldiers with a hearing impairment suggested that 34% of the US soldiers (n=300) fulfilled the criteria for probable PTSD. However, the former also filled in the Beck Depression Inventory, resulting in a smaller proportion moderately or severely depressed; 40%.

Abrams and colleagues found that 29.3% (n=123) of US veterans with a hearing impairment were depressed whereas 6.5% of the controls, US veterans without a hearing impairment, were depressed (n=370). In a separate study, military personnel with hearing loss were not more likely to report depression compared to those without hearing loss.

DEPRESSION
Levels of self-reported depression were highest among US veterans with a spinal cord injury (46.4%; n=168), compared to a study among Iran soldiers with a lower limb amputation (9.7%; n=31). However, the former also filled in the Beck Depression Inventory, resulting in a smaller proportion moderately or severely depressed; 40%.

Abrams and colleagues found that 29.3% (n=123) of US veterans with a hearing impairment were depressed whereas 6.5% of the controls, US veterans without a hearing impairment, were depressed (n=370). In a separate study, military personnel with hearing loss were not more likely to report depression compared to those without hearing loss.

ANXIETY
The levels of probable anxiety disorder ranged from 16.1% to 35.5% among Iranian soldiers with above knee amputations (self-reported anxiety; n=31) and UK service men (n=138) with an upper limb amputation, respectively. Among US veterans who were deployed on Operation Iraqi Freedom (OIF)/Operation Enduring Freedom (OEF), SCI, spinal cord injury.
soldiers with an extremity amputation, the diagnosis of probable clinical anxiety was considerable, 34% (n=582; figure 4).

SUBSTANCE MISUSE
More than a quarter of US veterans with a spinal cord injury self-reported alcoholism or intravenous drug use (26.2%; n=168). Gunawardena et al. suggested that only 2.2% (n=461) of the Sri Lankan soldiers with amputations had a substance abuse problem compared to 0.7% (n=461) of the controls (non-amputee civilians; figure 5).

PSYCHOLOGICAL AND SOMATIC SYMPTOMS OF DISTRESS
Levels of psychological distress were higher among Sri Lankan soldiers who had undergone an amputation (36%; n=461), compared to healthy controls (8.9%; n=461). Another study among permanently disabled Sri Lankan soldiers (n=408) suggested that a positive General Health Questionnaire score, measuring psychological distress, was associated with increased alcohol consumption. A study conducted in Nicaragua suggested that war-wounded soldiers (n=72) were more likely to be identified with probable psychological distress (33.3%) compared to those not wounded (9.8%; n=51; see online supplementary table S2; figure 6).

DISCUSSION
Principal findings
We identified 25 papers, reflecting 17 studies, which reported on the association between having predominantly a physical impairment and mental health problems among (ex-)military personnel. Overall, the reviewed studies indicate that mental health disorders including PTSD (range 2–59%), anxiety (range 16.1–35.5%), depression (range 9.7–46.4%) and psychological distress (range 13.4–36%) are prevalent and highly variable among (ex-)military personnel with an impairment. Substance misuse was less common, but still present (range 2.2–26.2%).

Strengths and weaknesses
A strength of the study was the search of four literature databases using a broad search strategy. Furthermore, the eligibility assessment of full-text articles and the critical appraisal of the studies included by two independent reviewers also strengthened the review. The present review has several weaknesses. First, only English language papers were included in the review. Second, the majority of the studies only investigated the mental well-being of personnel with an impairment at one point in time. Therefore, no causal inference can be made whether becoming impaired triggered or contributed to the development of mental health problems. Longitudinal studies following military personnel over time may provide more insight in the actual process of coping and adaptation when becoming impaired. Third, the type of measures used to assess mental health problems as well as cut-off points for diagnostic criteria varied widely, and findings are difficult to compare. However, combining these papers in a single review contributes to the broader understanding. Fourth, studies often lacked information that would have been helpful for the contextualisation and interpretation of the findings. For example, time since being impaired, actual cause of impairment, service arm, rank and details on combat exposure were often missing. Finally, the sample size of studies varied (range n=31–45 320) as well as the selection procedures and study populations. The above limitations are also reflected in a poor to moderate quality score of the studies (average 2.3). Owing to the heterogeneity of the studies included, the current review provides a broad overview on the
impact of impairment on the mental well-being in different military populations and provides directions for future research. Despite these limitations, the review has implications as military personnel are currently coming back with service attributable injuries and their physical and mental health needs careful consideration.

Comparison literature

There is a wealth of information on the prevalence of mental health disorders in military personnel. Therefore, we will only compare our results with the main UK, USA and other relevant (literature review) studies.

The US Millennium cohort study is a very large population-based cohort study that started in 2001 and aims to follow-up approximately 200,000 military personnel. Their baseline data suggested a prevalence of 3.2% for depression, 2% for anxiety, 12.6% for alcohol misuse and 2.4% for PTSD. Results from a large study conducted among four US combat infantry units recorded that predeployment levels of mental disorders (e.g., symptoms of anxiety, depression and PTSD) were between 9% and 15% compared to between 11% and 17% 3–4 months post-deployment to Iraq or Afghanistan. An extensive study carried out among 103,788 US veterans who had been deployed to Iraq or Afghanistan found that 13% of those who visited a veterans affair healthcare facility had a PTSD diagnosis, followed by depression and substance use disorder (both 5%).

A baseline study among UK Armed Forces personnel suggested a prevalence of 20% for symptoms of common mental disorders, 4% for probable PTSD and 13% for alcohol misuse after deployment to Iraq or Afghanistan. The findings from their follow-up study were comparable to the baseline study that included soldiers who had not been deployed and those deployed during the first stage of the operation in Iraq. Also 4% were identified as having probable PTSD and approximately 20% recorded symptoms of common mental disorders. Only a small increase was found in the level of alcohol misuse after deployment in the follow-up study (2007–2009) and in the levels of PTSD among those in combat-roles.

Woodhead et al (2011) examined the mental health of UK veterans and compared these with non-veterans matched for age and sex. Levels of PTSD and severe alcohol misuse were similar; 2.2% and 4.6% for the veterans and 2.9% and 7.6% for the non-veterans.

A literature review concerning the prevalence of combat-related PTSD among military personnel and veterans who had been deployed to Iraq suggested that the prevalence range of combat-related PTSD was higher among US veterans compared to UK veterans, between the 4–17% and 3–6%, respectively. According to the authors these different findings might be influenced by various study design factors as well as issues related to the deployment and sociopolitical and cultural context.

Figure 6 Forest plot describing the prevalence of distress (psychological or somatic) across studies.

Review

Delimar et al suggested that the PTSD prevalence rate was highest among soldiers with non-disabling injuries, followed by those with a permanent disabling injury and healthy active duty soldiers. The authors suggested that those with a non-disabling injury experienced more stress because they feared being sent back to the front. Furthermore, they may have experienced a stronger sense of helplessness during the traumatic event as they often did not lose consciousness, in contrast to soldiers with permanent disabling injuries. Amputees were less likely to have PTSD compared to non-amputees with serious extremity injuries in a study conducted among US military personnel, 18.1% vs 32.1%, respectively. Several factors including differences in care after the injury, social and emotional support from colleagues and/or family may explain the difference but further investigation is necessary. It is important to note that these studies were cross-sectional in design and no information is available about the onset of the mental health disorder. Participants could have experienced other traumatic life events before or after their injury that may have triggered the development of PTSD or other mental health disorders.

The majority of the studies included in the review focused solely on (ex-)military personnel with an amputation. Besides high levels of PTSD, also substantial levels of depression,
amputation.21 This is followed by a gradual decline to levels
limb amputation concluded that depression and anxiety are
independent of the funders.
Blind Veterans UK. SAMS and EMM are funded by Blind Veterans UK.
Funding
the articles included and commented on the manuscript. CM and SJ rated
the health of the patient needs evaluation. Adaptation and coping
skills should be provided to facilitate the psychosocial challenges
(ex-)military personnel with an impairment face.

Conclusions
Common mental health disorders are frequently reported among
(ex-)military personnel with a physical impairment but
rates vary considerably. Only few studies have looked into the
association between various mental health disorders and differ-
ent forms of impairments. Therefore, the results should be
interpreted with caution and research should be directed into
comparing prevalence rates of mental health disorders across
impairment types and factors impacting this association.
