Authors’ reply to letters from Egilman et al and Oliver et al

Dr Egilman and colleagues claim our report1 implies that chrysotile does not cause mesothelioma. So did the International Chrysotile Association, the website of which highlighted our paper with the misleading headline ‘Reliable scientific data confirms negligible role of chrysotile in UK patients with asbestos-related lung disease’.2 Our results are consistent with the strong evidence that chrysotile did not cause a large proportion of UK mesotheliomas, but they certainly do not show that the risk is negligible. We said ‘the rapid clearance of chrysotile from the lung with a half-life of a few months explains its virtual absence in our samples, and implies with a half-life of a few months explains its rapid clearance of chrysotile from the lung’.

Dr Egilman and colleagues also criticise our analysis of lung rather than pleural tissue and our restriction of transmission electron microscope (TEM) counting to asbestos fibres longer than 5 μm. We observed that ‘for fibres of specified dimension it seems reasonable to assume a linear relationship between inhaled dose, fibre concentration in pleural stomata and our measurements in lung parenchyma’. After reviewing the human, animal and in vitro evidence, an expert panel convened by the US Agency for Toxic Substances and Disease Registry concluded that ‘There is a strong weight of evidence that asbestos and synthetic vitreous fibers shorter than 5 μm are unlikely to cause cancer in humans’.3 Our protocol for anonymised sample preparation used minimal ultrasonic treatment and did not involve freeze-drying, and we used a single laboratory. They cite the assumption in 1978 that mesotheliomas in the Rochdale factory were caused by chrysotile.4 This predated the admission by the company that over 10 000 tonnes of crocidolite were also processed between 1932 and 1968.5

Dr Oliver and colleagues missed several details. There were no next-of-kin or proxy interviews, our statistical definition of asbestos-related lung cancer did not involve asbestosis (which would be biased) and we showed that our estimated ratio of mesothelioma to asbestos-related lung cancer is consistent with two population-based UK studies. That ‘the gold standard for asbestos-exposure assessment is the occupational history, not fiber burden’ is contradicted by the dose–response we observed within occupational groups and is particularly unhelpful in relation to Britain’s high mesothelioma rate in both sexes due to environmental asbestos exposure from unidentified sources.6 The strong correlation we observed between lung burden and mesothelioma risk will not ‘imperil the diagnosis of asbestosis-related disease, victim compensation, and public health measures aimed at primary and secondary prevention’. Our results, together with lung burdens in younger people, will enable the risks associated with current exposures from asbestos in buildings to be estimated, informing effective disease prevention.
